COMPUTER ARCHITECTURE

A Quantitative Approach

MK
MORGAN KAUFMANN

Computer Architecture Formulas

1. $CPU\ time = \text{Instruction count} \times \text{Clock cycles per instruction} \times \text{Clock cycle time}$
2. $X\text{ is }n\text{ times faster than }Y: n = \text{Execution time}_Y / \text{Execution time}_X = \text{Performance}_X / \text{Performance}_Y$
3. $Amdahl's\ Law: \text{Speedup}_{\text{overall}} = \frac{\text{Execution time}_{\text{old}}}{\text{Execution time}_{\text{new}}} = \frac{1}{(1 - \text{Fraction}_{\text{enhanced}}) + \frac{\text{Fraction}_{\text{enhanced}}}{\text{Speedup}_{\text{enhanced}}}}$
4. $Energy_{\text{dynamic}} \propto 1/2 \times \text{Capacitive load} \times \text{Voltage}^2$
5. $Power_{\text{dynamic}} \propto 1/2 \times \text{Capacitive load} \times \text{Voltage}^2 \times \text{Frequency switched}$
6. $Power_{\text{static}} \propto \text{Current}_{\text{static}} \times \text{Voltage}$
7. $Availability = \text{Mean time to fail} / (\text{Mean time to fail} + \text{Mean time to repair})$
8. $Die\ yield = \text{Wafer yield} \times 1 / (1 + \text{Defects per unit area} \times \text{Die area})^N$

where Wafer yield accounts for wafers that are so bad they need not be tested and N is a parameter called the process-complexity factor, a measure of manufacturing difficulty. N ranges from 11.5 to 15.5 in 2011.

9. *Means—arithmetic (AM), weighted arithmetic (WAM), and geometric (GM):*

$$AM = \frac{1}{n} \sum_{i=1}^n \text{Time}_i \quad WAM = \sum_{i=1}^n \text{Weight}_i \times \text{Time}_i \quad GM = \sqrt[n]{\prod_{i=1}^n \text{Time}_i}$$

where Time_i is the execution time for the i th program of a total of n in the workload, Weight_i is the weighting of the i th program in the workload.

10. $\text{Average memory-access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$
11. $\text{Misses per instruction} = \text{Miss rate} \times \text{Memory access per instruction}$
12. $\text{Cache index size: } 2^{\text{index}} = \text{Cache size} / (\text{Block size} \times \text{Set associativity})$
13. $\text{Power Utilization Effectiveness (PUE) of a Warehouse Scale Computer} = \frac{\text{Total Facility Power}}{\text{IT Equipment Power}}$

Rules of Thumb

1. *Amdahl/Case Rule:* A balanced computer system needs about 1 MB of main memory capacity and 1 megabit per second of I/O bandwidth per MIPS of CPU performance.
2. *90/10 Locality Rule:* A program executes about 90% of its instructions in 10% of its code.
3. *Bandwidth Rule:* Bandwidth grows by at least the square of the improvement in latency.
4. *2:1 Cache Rule:* The miss rate of a direct-mapped cache of size N is about the same as a two-way set-associative cache of size $N/2$.
5. *Dependability Rule:* Design with no single point of failure.
6. *Watt-Year Rule:* The fully burdened cost of a Watt per year in a Warehouse Scale Computer in North America in 2011, including the cost of amortizing the power and cooling infrastructure, is about \$2.

In Praise of *Computer Architecture: A Quantitative Approach* Sixth Edition

“Although important concepts of architecture are timeless, this edition has been thoroughly updated with the latest technology developments, costs, examples, and references. Keeping pace with recent developments in open-sourced architecture, the instruction set architecture used in the book has been updated to use the RISC-V ISA.”

—from the foreword by Norman P. Jouppi, Google

“*Computer Architecture: A Quantitative Approach* is a classic that, like fine wine, just keeps getting better. I bought my first copy as I finished up my undergraduate degree and it remains one of my most frequently referenced texts today.”

—James Hamilton, Amazon Web Service

“Hennessy and Patterson wrote the first edition of this book when graduate students built computers with 50,000 transistors. Today, warehouse-size computers contain that many servers, each consisting of dozens of independent processors and billions of transistors. The evolution of computer architecture has been rapid and relentless, but *Computer Architecture: A Quantitative Approach* has kept pace, with each edition accurately explaining and analyzing the important emerging ideas that make this field so exciting.”

—James Larus, Microsoft Research

“Another timely and relevant update to a classic, once again also serving as a window into the relentless and exciting evolution of computer architecture! The new discussions in this edition on the slowing of Moore's law and implications for future systems are must-reads for both computer architects and practitioners working on broader systems.”

—Parthasarathy (Partha) Ranganathan, Google

“I love the ‘Quantitative Approach’ books because they are written by engineers, for engineers. John Hennessy and Dave Patterson show the limits imposed by mathematics and the possibilities enabled by materials science. Then they teach through real-world examples how architects analyze, measure, and compromise to build working systems. This sixth edition comes at a critical time: Moore's Law is fading just as deep learning demands unprecedented compute cycles. The new chapter on domain-specific architectures documents a number of promising approaches and prophesies a rebirth in computer architecture. Like the scholars of the European Renaissance, computer architects must understand our own history, and then combine the lessons of that history with new techniques to remake the world.”

—Cliff Young, Google

Computer Architecture

A Quantitative Approach

Sixth Edition

John L. Hennessy is a Professor of Electrical Engineering and Computer Science at Stanford University, where he has been a member of the faculty since 1977 and was, from 2000 to 2016, its 10th President. He currently serves as the Director of the Knight-Hennessy Fellowship, which provides graduate fellowships to potential future leaders. Hennessy is a Fellow of the IEEE and ACM, a member of the National Academy of Engineering, the National Academy of Science, and the American Philosophical Society, and a Fellow of the American Academy of Arts and Sciences. Among his many awards are the 2001 Eckert-Mauchly Award for his contributions to RISC technology, the 2001 Seymour Cray Computer Engineering Award, and the 2000 John von Neumann Award, which he shared with David Patterson. He has also received 10 honorary doctorates.

In 1981, he started the MIPS project at Stanford with a handful of graduate students. After completing the project in 1984, he took a leave from the university to cofound MIPS Computer Systems, which developed one of the first commercial RISC microprocessors. As of 2017, over 5 billion MIPS microprocessors have been shipped in devices ranging from video games and palmtop computers to laser printers and network switches. Hennessy subsequently led the DASH (Director Architecture for Shared Memory) project, which prototyped the first scalable cache coherent multiprocessor; many of the key ideas have been adopted in modern multiprocessors. In addition to his technical activities and university responsibilities, he has continued to work with numerous start-ups, both as an early-stage advisor and an investor.

David A. Patterson became a Distinguished Engineer at Google in 2016 after 40 years as a UC Berkeley professor. He joined UC Berkeley immediately after graduating from UCLA. He still spends a day a week in Berkeley as an Emeritus Professor of Computer Science. His teaching has been honored by the Distinguished Teaching Award from the University of California, the Karlstrom Award from ACM, and the Mulligan Education Medal and Undergraduate Teaching Award from IEEE. Patterson received the IEEE Technical Achievement Award and the ACM Eckert-Mauchly Award for contributions to RISC, and he shared the IEEE Johnson Information Storage Award for contributions to RAID. He also shared the IEEE John von Neumann Medal and the C & C Prize with John Hennessy. Like his co-author, Patterson is a Fellow of the American Academy of Arts and Sciences, the Computer History Museum, ACM, and IEEE, and he was elected to the National Academy of Engineering, the National Academy of Sciences, and the Silicon Valley Engineering Hall of Fame. He served on the Information Technology Advisory Committee to the President of the United States, as chair of the CS division in the Berkeley EECS department, as chair of the Computing Research Association, and as President of ACM. This record led to Distinguished Service Awards from ACM, CRA, and SIGARCH. He is currently Vice-Chair of the Board of Directors of the RISC-V Foundation.

At Berkeley, Patterson led the design and implementation of RISC I, likely the first VLSI reduced instruction set computer, and the foundation of the commercial SPARC architecture. He was a leader of the Redundant Arrays of Inexpensive Disks (RAID) project, which led to dependable storage systems from many companies. He was also involved in the Network of Workstations (NOW) project, which led to cluster technology used by Internet companies and later to cloud computing. His current interests are in designing domain-specific architectures for machine learning, spreading the word on the open RISC-V instruction set architecture, and in helping the UC Berkeley RISELab (Real-time Intelligent Secure Execution).

Foreword

by Norman P. Jouppi, Google

Much of the improvement in computer performance over the last 40 years has been provided by computer architecture advancements that have leveraged Moore's Law and Dennard scaling to build larger and more parallel systems. Moore's Law is the observation that the maximum number of transistors in an integrated circuit doubles approximately every two years. Dennard scaling refers to the reduction of MOS supply voltage in concert with the scaling of feature sizes, so that as transistors get smaller, their power density stays roughly constant. With the end of Dennard scaling a decade ago, and the recent slowdown of Moore's Law due to a combination of physical limitations and economic factors, the sixth edition of the preeminent textbook for our field couldn't be more timely. Here are some reasons.

First, because domain-specific architectures can provide equivalent performance and power benefits of three or more historical generations of Moore's Law and Dennard scaling, they now can provide better implementations than may ever be possible with future scaling of general-purpose architectures. And with the diverse application space of computers today, there are many potential areas for architectural innovation with domain-specific architectures. Second, high-quality implementations of open-source architectures now have a much longer lifetime due to the slowdown in Moore's Law. This gives them more opportunities for continued optimization and refinement, and hence makes them more attractive. Third, with the slowing of Moore's Law, different technology components have been scaling heterogeneously. Furthermore, new technologies such as 2.5D stacking, new nonvolatile memories, and optical interconnects have been developed to provide more than Moore's Law can supply alone. To use these new technologies and nonhomogeneous scaling effectively, fundamental design decisions need to be reexamined from first principles. Hence it is important for students, professors, and practitioners in the industry to be skilled in a wide range of both old and new architectural techniques. All told, I believe this is the most exciting time in computer architecture since the industrial exploitation of instruction-level parallelism in microprocessors 25 years ago.

The largest change in this edition is the addition of a new chapter on domain-specific architectures. It's long been known that customized domain-specific architectures can have higher performance, lower power, and require less silicon area than general-purpose processor implementations. However when general-purpose

processors were increasing in single-threaded performance by 40% per year (see Fig. 1.11), the extra time to market required to develop a custom architecture vs. using a leading-edge standard microprocessor could cause the custom architecture to lose much of its advantage. In contrast, today single-core performance is improving very slowly, meaning that the benefits of custom architectures will not be made obsolete by general-purpose processors for a very long time, if ever. [Chapter 7](#) covers several domain-specific architectures. Deep neural networks have very high computation requirements but lower data precision requirements – this combination can benefit significantly from custom architectures. Two example architectures and implementations for deep neural networks are presented: one optimized for inference and a second optimized for training. Image processing is another example domain; it also has high computation demands and benefits from lower-precision data types. Furthermore, since it is often found in mobile devices, the power savings from custom architectures are also very valuable. Finally, by nature of their reprogrammability, FPGA-based accelerators can be used to implement a variety of different domain-specific architectures on a single device. They also can benefit more irregular applications that are frequently updated, like accelerating internet search.

Although important concepts of architecture are timeless, this edition has been thoroughly updated with the latest technology developments, costs, examples, and references. Keeping pace with recent developments in open-sourced architecture, the instruction set architecture used in the book has been updated to use the RISC-V ISA.

On a personal note, after enjoying the privilege of working with John as a graduate student, I am now enjoying the privilege of working with Dave at Google. What an amazing duo!

Contents

Foreword	ix
Preface	xvii

Chapter 3 **Instruction-Level Parallelism and Its Exploitation**

3.1	Instruction-Level Parallelism: Concepts and Challenges	168
3.2	Basic Compiler Techniques for Exposing ILP	176
3.3	Reducing Branch Costs With Advanced Branch Prediction	182
3.4	Overcoming Data Hazards With Dynamic Scheduling	191
3.5	Dynamic Scheduling: Examples and the Algorithm	201
3.6	Hardware-Based Speculation	208
3.7	Exploiting ILP Using Multiple Issue and Static Scheduling	218
3.8	Exploiting ILP Using Dynamic Scheduling, Multiple Issue, and Speculation	222
3.9	Advanced Techniques for Instruction Delivery and Speculation	228
3.10	Cross-Cutting Issues	240
3.11	Multithreading: Exploiting Thread-Level Parallelism to Improve Uniprocessor Throughput	242
3.12	Putting It All Together: The Intel Core i7 6700 and ARM Cortex-A53	247
3.13	Fallacies and Pitfalls	258
3.14	Concluding Remarks: What's Ahead?	264
3.15	Historical Perspective and References	266
	Case Studies and Exercises by Jason D. Bakos and Robert P. Colwell	266

Chapter 4 **Data-Level Parallelism in Vector, SIMD, and GPU Architectures**

4.1	Introduction	282
4.2	Vector Architecture	283
4.3	SIMD Instruction Set Extensions for Multimedia	304
4.4	Graphics Processing Units	310
4.5	Detecting and Enhancing Loop-Level Parallelism	336
4.6	Cross-Cutting Issues	345
4.7	Putting It All Together: Embedded Versus Server GPUs and Tesla Versus Core i7	346
4.8	Fallacies and Pitfalls	353
4.9	Concluding Remarks	357
4.10	Historical Perspective and References	357
	Case Study and Exercises by Jason D. Bakos	357

Chapter 5 **Thread-Level Parallelism**

5.1	Introduction	368
5.2	Centralized Shared-Memory Architectures	377
5.3	Performance of Symmetric Shared-Memory Multiprocessors	393

	5.4	Distributed Shared-Memory and Directory-Based Coherence	404
	5.5	Synchronization: The Basics	412
	5.6	Models of Memory Consistency: An Introduction	417
	5.7	Cross-Cutting Issues	422
	5.8	Putting It All Together: Multicore Processors and Their Performance	426
	5.9	Fallacies and Pitfalls	438
	5.10	The Future of Multicore Scaling	442
	5.11	Concluding Remarks	444
	5.12	Historical Perspectives and References	445
		Case Studies and Exercises by Amr Zaky and David A. Wood	446
Chapter 6		Warehouse-Scale Computers to Exploit Request-Level and Data-Level Parallelism	
	6.1	Introduction	466
	6.2	Programming Models and Workloads for Warehouse-Scale Computers	471
	6.3	Computer Architecture of Warehouse-Scale Computers	477
	6.4	The Efficiency and Cost of Warehouse-Scale Computers	482
	6.5	Cloud Computing: The Return of Utility Computing	490
	6.6	Cross-Cutting Issues	501
	6.7	Putting It All Together: A Google Warehouse-Scale Computer	503
	6.8	Fallacies and Pitfalls	514
	6.9	Concluding Remarks	518
	6.10	Historical Perspectives and References	519
		Case Studies and Exercises by Parthasarathy Ranganathan	519
Chapter 7		Domain-Specific Architectures	
	7.1	Introduction	540
	7.2	Guidelines for DSAs	543
	7.3	Example Domain: Deep Neural Networks	544
	7.4	Google's Tensor Processing Unit, an Inference Data Center Accelerator	557
	7.5	Microsoft Catapult, a Flexible Data Center Accelerator	567
	7.6	Intel Crest, a Data Center Accelerator for Training	579
	7.7	Pixel Visual Core, a Personal Mobile Device Image Processing Unit	579
	7.8	Cross-Cutting Issues	592
	7.9	Putting It All Together: CPUs Versus GPUs Versus DNN Accelerators	595
	7.10	Fallacies and Pitfalls	602
	7.11	Concluding Remarks	604
	7.12	Historical Perspectives and References	606
		Case Studies and Exercises by Cliff Young	606

Appendix A **Instruction Set Principles**

A.1	Introduction	A-2
A.2	Classifying Instruction Set Architectures	A-3
A.3	Memory Addressing	A-7
A.4	Type and Size of Operands	A-13
A.5	Operations in the Instruction Set	A-15
A.6	Instructions for Control Flow	A-16
A.7	Encoding an Instruction Set	A-21
A.8	Cross-Cutting Issues: The Role of Compilers	A-24
A.9	Putting It All Together: The RISC-V Architecture	A-33
A.10	Fallacies and Pitfalls	A-42
A.11	Concluding Remarks	A-46
A.12	Historical Perspective and References	A-47
	Exercises by Gregory D. Peterson	A-47

Appendix B **Review of Memory Hierarchy**

B.1	Introduction	B-2
B.2	Cache Performance	B-15
B.3	Six Basic Cache Optimizations	B-22
B.4	Virtual Memory	B-40
B.5	Protection and Examples of Virtual Memory	B-49
B.6	Fallacies and Pitfalls	B-57
B.7	Concluding Remarks	B-59
B.8	Historical Perspective and References	B-59
	Exercises by Amr Zaky	B-60

Appendix C **Pipelining: Basic and Intermediate Concepts**

C.1	Introduction	C-2
C.2	The Major Hurdle of Pipelining—Pipeline Hazards	C-10
C.3	How Is Pipelining Implemented?	C-26
C.4	What Makes Pipelining Hard to Implement?	C-37
C.5	Extending the RISC V Integer Pipeline to Handle Multicycle Operations	C-45
C.6	Putting It All Together: The MIPS R4000 Pipeline	C-55
C.7	Cross-Cutting Issues	C-65
C.8	Fallacies and Pitfalls	C-70
C.9	Concluding Remarks	C-71
C.10	Historical Perspective and References	C-71
	Updated Exercises by Diana Franklin	C-71

Preface

Why We Wrote This Book

Through six editions of this book, our goal has been to describe the basic principles underlying what will be tomorrow's technological developments. Our excitement about the opportunities in computer architecture has not abated, and we echo what we said about the field in the first edition: "It is not a dreary science of paper machines that will never work. No! It's a discipline of keen intellectual interest, requiring the balance of marketplace forces to cost-performance-power, leading to glorious failures and some notable successes."

Our primary objective in writing our first book was to change the way people learn and think about computer architecture. We feel this goal is still valid and important. The field is changing daily and must be studied with real examples and measurements on real computers, rather than simply as a collection of definitions and designs that will never need to be realized. We offer an enthusiastic welcome to anyone who came along with us in the past, as well as to those who are joining us now. Either way, we can promise the same quantitative approach to, and analysis of, real systems.

As with earlier versions, we have strived to produce a new edition that will continue to be as relevant for professional engineers and architects as it is for those involved in advanced computer architecture and design courses. Like the first edition, this edition has a sharp focus on new platforms—personal mobile devices and warehouse-scale computers—and new architectures—specifically, domain-specific architectures. As much as its predecessors, this edition aims to demystify computer architecture through an emphasis on cost-performance-energy trade-offs and good engineering design. We believe that the field has continued to mature and move toward the rigorous quantitative foundation of long-established scientific and engineering disciplines.

This Edition

The ending of Moore’s Law and Dennard scaling is having as profound effect on computer architecture as did the switch to multicore. We retain the focus on the extremes in size of computing, with personal mobile devices (PMDs) such as cell phones and tablets as the clients and warehouse-scale computers offering cloud computing as the server. We also maintain the other theme of parallelism in all its forms: *data-level parallelism (DLP)* in Chapters 1 and 4, *instruction-level parallelism (ILP)* in Chapter 3, *thread-level parallelism* in Chapter 5, and *request-level parallelism (RLP)* in Chapter 6.

The most pervasive change in this edition is switching from MIPS to the RISC-V instruction set. We suspect this modern, modular, open instruction set may become a significant force in the information technology industry. It may become as important in computer architecture as Linux is for operating systems.

The newcomer in this edition is Chapter 7, which introduces domain-specific architectures with several concrete examples from industry.

As before, the first three appendices in the book give basics on the RISC-V instruction set, memory hierarchy, and pipelining for readers who have not read a book like *Computer Organization and Design*. To keep costs down but still supply supplemental material that is of interest to some readers, available online at <https://www.elsevier.com/books-and-journals/book-companion/9780128119051> are nine more appendices. There are more pages in these appendices than there are in this book!

This edition continues the tradition of using real-world examples to demonstrate the ideas, and the “Putting It All Together” sections are brand new. The “Putting It All Together” sections of this edition include the pipeline organizations and memory hierarchies of the ARM Cortex A8 processor, the Intel core i7 processor, the NVIDIA GTX-280 and GTX-480 GPUs, and one of the Google warehouse-scale computers.

Topic Selection and Organization

As before, we have taken a conservative approach to topic selection, for there are many more interesting ideas in the field than can reasonably be covered in a treatment of basic principles. We have steered away from a comprehensive survey of every architecture a reader might encounter. Instead, our presentation focuses on core concepts likely to be found in any new machine. The key criterion remains that of selecting ideas that have been examined and utilized successfully enough to permit their discussion in quantitative terms.

Our intent has always been to focus on material that is not available in equivalent form from other sources, so we continue to emphasize advanced content wherever possible. Indeed, there are several systems here whose descriptions cannot be found in the literature. (Readers interested strictly in a more basic introduction to computer architecture should read *Computer Organization and Design: The Hardware/Software Interface*.)

An Overview of the Content

[Chapter 1](#) includes formulas for energy, static power, dynamic power, integrated circuit costs, reliability, and availability. (These formulas are also found on the front inside cover.) Our hope is that these topics can be used through the rest of the book. In addition to the classic quantitative principles of computer design and performance measurement, it shows the slowing of performance improvement of general-purpose microprocessors, which is one inspiration for domain-specific architectures.

Our view is that the instruction set architecture is playing less of a role today than in 1990, so we moved this material to [Appendix A](#). It now uses the RISC-V architecture. (For quick review, a summary of the RISC-V ISA can be found on the back inside cover.) For fans of ISAs, [Appendix K](#) was revised for this edition and covers 8 RISC architectures (5 for desktop and server use and 3 for embedded use), the 80×86, the DEC VAX, and the IBM 360/370.

We then move onto memory hierarchy in [Chapter 2](#), since it is easy to apply the cost-performance-energy principles to this material, and memory is a critical resource for the rest of the chapters. As in the past edition, [Appendix B](#) contains an introductory review of cache principles, which is available in case you need it. [Chapter 2](#) discusses 10 advanced optimizations of caches. The chapter includes virtual machines, which offer advantages in protection, software management, and hardware management, and play an important role in cloud computing. In addition to covering SRAM and DRAM technologies, the chapter includes new material both on Flash memory and on the use of stacked die packaging for extending the memory hierarchy. The PIAT examples are the ARM Cortex A8, which is used in PMDs, and the Intel Core i7, which is used in servers.

[Chapter 3](#) covers the exploitation of instruction-level parallelism in high-performance processors, including superscalar execution, branch prediction (including the new tagged hybrid predictors), speculation, dynamic scheduling, and simultaneous multithreading. As mentioned earlier, [Appendix C](#) is a review of pipelining in case you need it. [Chapter 3](#) also surveys the limits of ILP. Like [Chapter 2](#), the PIAT examples are again the ARM Cortex A8 and the Intel Core i7. While the third edition contained a great deal on Itanium and VLIW, this material is now in [Appendix H](#), indicating our view that this architecture did not live up to the earlier claims.

The increasing importance of multimedia applications such as games and video processing has also increased the importance of architectures that can exploit data level parallelism. In particular, there is a rising interest in computing using graphical processing units (GPUs), yet few architects understand how GPUs really work. We decided to write a new chapter in large part to unveil this new style of computer architecture. [Chapter 4](#) starts with an introduction to vector architectures, which acts as a foundation on which to build explanations of multimedia SIMD instruction set extensions and GPUs. ([Appendix G](#) goes into even more depth on vector architectures.) This chapter introduces the Roofline performance model and then uses it to compare the Intel Core i7 and the NVIDIA GTX 280 and GTX 480 GPUs. The chapter also describes the Tegra 2 GPU for PMDs.

[Chapter 5](#) describes multicore processors. It explores symmetric and distributed-memory architectures, examining both organizational principles and performance. The primary additions to this chapter include more comparison of multicore organizations, including the organization of multicore-multilevel caches, multicore coherence schemes, and on-chip multicore interconnect. Topics in synchronization and memory consistency models are next. The example is the Intel Core i7. Readers interested in more depth on interconnection networks should read [Appendix F](#), and those interested in larger scale multiprocessors and scientific applications should read [Appendix I](#).

[Chapter 6](#) describes warehouse-scale computers (WSCs). It was extensively revised based on help from engineers at Google and Amazon Web Services. This chapter integrates details on design, cost, and performance of WSCs that few architects are aware of. It starts with the popular MapReduce programming model before describing the architecture and physical implementation of WSCs, including cost. The costs allow us to explain the emergence of cloud computing, whereby it can be cheaper to compute using WSCs in the cloud than in your local datacenter. The PIAT example is a description of a Google WSC that includes information published for the first time in this book.

The new [Chapter 7](#) motivates the need for Domain-Specific Architectures (DSAs). It draws guiding principles for DSAs based on the four examples of DSAs. Each DSA corresponds to chips that have been deployed in commercial settings. We also explain why we expect a renaissance in computer architecture via DSAs given that single-thread performance of general-purpose microprocessors has stalled.

This brings us to [Appendices A through M](#). [Appendix A](#) covers principles of ISAs, including RISC-V, and [Appendix K](#) describes 64-bit versions of RISC V, ARM, MIPS, Power, and SPARC and their multimedia extensions. It also includes some classic architectures (80x86, VAX, and IBM 360/370) and popular embedded instruction sets (Thumb-2, microMIPS, and RISC V C). [Appendix H](#) is related, in that it covers architectures and compilers for VLIW ISAs.

As mentioned earlier, [Appendix B](#) and [Appendix C](#) are tutorials on basic caching and pipelining concepts. Readers relatively new to caching should read [Appendix B](#) before [Chapter 2](#), and those new to pipelining should read [Appendix C](#) before [Chapter 3](#).

[Appendix D](#), “Storage Systems,” has an expanded discussion of reliability and availability, a tutorial on RAID with a description of RAID 6 schemes, and rarely found failure statistics of real systems. It continues to provide an introduction to queuing theory and I/O performance benchmarks. We evaluate the cost, performance, and reliability of a real cluster: the Internet Archive. The “Putting It All Together” example is the NetApp FAS6000 filer.

[Appendix E](#), by Thomas M. Conte, consolidates the embedded material in one place.

[Appendix F](#), on interconnection networks, is revised by Timothy M. Pinkston and José Duato. [Appendix G](#), written originally by Krste Asanović, includes a description of vector processors. We think these two appendices are some of the best material we know of on each topic.

Appendix H describes VLIW and EPIC, the architecture of Itanium.

Appendix I describes parallel processing applications and coherence protocols for larger-scale, shared-memory multiprocessing. Appendix J, by David Goldberg, describes computer arithmetic.

Appendix L, by Abhishek Bhattacharjee, is new and discusses advanced techniques for memory management, focusing on support for virtual machines and design of address translation for very large address spaces. With the growth in clouds processors, these architectural enhancements are becoming more important.

Appendix M collects the “Historical Perspective and References” from each chapter into a single appendix. It attempts to give proper credit for the ideas in each chapter and a sense of the history surrounding the inventions. We like to think of this as presenting the human drama of computer design. It also supplies references that the student of architecture may want to pursue. If you have time, we recommend reading some of the classic papers in the field that are mentioned in these sections. It is both enjoyable and educational to hear the ideas directly from the creators. “Historical Perspective” was one of the most popular sections of prior editions.

Navigating the Text

There is no single best order in which to approach these chapters and appendices, except that all readers should start with [Chapter 1](#). If you don’t want to read everything, here are some suggested sequences:

- *Memory Hierarchy*: [Appendix B](#), [Chapter 2](#), and Appendices D and M.
- *Instruction-Level Parallelism*: [Appendix C](#), [Chapter 3](#), and Appendix H
- *Data-Level Parallelism*: Chapters [4](#), [6](#), and [7](#), Appendix G
- *Thread-Level Parallelism*: [Chapter 5](#), Appendices F and I
- *Request-Level Parallelism*: [Chapter 6](#)
- *ISA*: Appendices A and K

Appendix E can be read at any time, but it might work best if read after the ISA and cache sequences. Appendix J can be read whenever arithmetic moves you. You should read the corresponding portion of Appendix M after you complete each chapter.

Chapter Structure

The material we have selected has been stretched upon a consistent framework that is followed in each chapter. We start by explaining the ideas of a chapter. These ideas are followed by a “Crosscutting Issues” section, a feature that shows how the ideas covered in one chapter interact with those given in other chapters. This is

followed by a “Putting It All Together” section that ties these ideas together by showing how they are used in a real machine.

Next in the sequence is “Fallacies and Pitfalls,” which lets readers learn from the mistakes of others. We show examples of common misunderstandings and architectural traps that are difficult to avoid even when you know they are lying in wait for you. The “Fallacies and Pitfalls” sections is one of the most popular sections of the book. Each chapter ends with a “Concluding Remarks” section.

Case Studies With Exercises

Each chapter ends with case studies and accompanying exercises. Authored by experts in industry and academia, the case studies explore key chapter concepts and verify understanding through increasingly challenging exercises. Instructors should find the case studies sufficiently detailed and robust to allow them to create their own additional exercises.

Brackets for each exercise (<chapter.section>) indicate the text sections of primary relevance to completing the exercise. We hope this helps readers to avoid exercises for which they haven’t read the corresponding section, in addition to providing the source for review. Exercises are rated, to give the reader a sense of the amount of time required to complete an exercise:

- [10] Less than 5 min (to read and understand)
- [15] 5–15 min for a full answer
- [20] 15–20 min for a full answer
- [25] 1 h for a full written answer
- [30] Short programming project: less than 1 full day of programming
- [40] Significant programming project: 2 weeks of elapsed time
- [Discussion] Topic for discussion with others

Solutions to the case studies and exercises are available for instructors who register at *textbooks.elsevier.com*.

Supplemental Materials

A variety of resources are available online at <https://www.elsevier.com/books/computer-architecture/hennessy/978-0-12-811905-1>, including the following:

- Reference appendices, some guest authored by subject experts, covering a range of advanced topics
- Historical perspectives material that explores the development of the key ideas presented in each of the chapters in the text

- Instructor slides in PowerPoint
- Figures from the book in PDF, EPS, and PPT formats
- Links to related material on the Web
- List of errata

New materials and links to other resources available on the Web will be added on a regular basis.

Helping Improve This Book

Finally, it is possible to make money while reading this book. (Talk about cost performance!) If you read the Acknowledgments that follow, you will see that we went to great lengths to correct mistakes. Since a book goes through many printings, we have the opportunity to make even more corrections. If you uncover any remaining resilient bugs, please contact the publisher by electronic mail (ca6bugs@mkp.com).

We welcome general comments to the text and invite you to send them to a separate email address at ca6comments@mkp.com.

Concluding Remarks

Once again, this book is a true co-authorship, with each of us writing half the chapters and an equal share of the appendices. We can't imagine how long it would have taken without someone else doing half the work, offering inspiration when the task seemed hopeless, providing the key insight to explain a difficult concept, supplying over-the-weekend reviews of chapters, and commiserating when the weight of our other obligations made it hard to pick up the pen.

Thus, once again, we share equally the blame for what you are about to read.

Acknowledgments

Although this is only the sixth edition of this book, we have actually created ten different versions of the text: three versions of the first edition (alpha, beta, and final) and two versions of the second, third, and fourth editions (beta and final). Along the way, we have received help from hundreds of reviewers and users. Each of these people has helped make this book better. Thus, we have chosen to list all of the people who have made contributions to some version of this book.

Contributors to the Sixth Edition

Like prior editions, this is a community effort that involves scores of volunteers. Without their help, this edition would not be nearly as polished.

Reviewers

Jason D. Bakos, University of South Carolina; Rajeev Balasubramonian, University of Utah; Jose Delgado-Frias, Washington State University; Diana Franklin, The University of Chicago; Norman P. Jouppi, Google; Hugh C. Lauer, Worcester Polytechnic Institute; Gregory Peterson, University of Tennessee; Bill Pierce, Hood College; Parthasarathy Ranganathan, Google; William H. Robinson, Vanderbilt University; Pat Stakem, Johns Hopkins University; Cliff Young, Google; Amr Zaky, University of Santa Clara; Gerald Zarnett, Ryerson University; Huiyang Zhou, North Carolina State University.

Members of the University of California-Berkeley Par Lab and RAD Lab who gave frequent reviews of Chapters 1, 4, and 6 and shaped the explanation of GPUs and WSCs: Krste Asanović, Michael Armbrust, Scott Beamer, Sarah Bird, Bryan Catanzaro, Jike Chong, Henry Cook, Derrick Coetzee, Randy Katz, Yunsup Lee, Leo Meyervich, Mark Murphy, Zhangxi Tan, Vasily Volkov, and Andrew Waterman.

Appendices

Krste Asanović, University of California, Berkeley (Appendix G); Abhishek Bhattacharjee, Rutgers University ([Appendix L](#)); Thomas M. Conte, North Carolina State University ([Appendix E](#)); José Duato, Universitat Politècnica de

València and Simula ([Appendix F](#)); David Goldberg, Xerox PARC ([Appendix J](#)); Timothy M. Pinkston, University of Southern California ([Appendix F](#)).

José Flich of the Universidad Politécnica de Valencia provided significant contributions to the updating of [Appendix F](#).

Case Studies With Exercises

Jason D. Bakos, University of South Carolina (Chapters [3](#) and [4](#)); Rajeev Balasubramanian, University of Utah ([Chapter 2](#)); Diana Franklin, The University of Chicago ([Chapter 1](#) and Appendix C); Norman P. Jouppi, Google, ([Chapter 2](#)); Naveen Muralimanohar, HP Labs ([Chapter 2](#)); Gregory Peterson, University of Tennessee ([Appendix A](#)); Parthasarathy Ranganathan, Google (Chapter 6); Cliff Young, Google ([Chapter 7](#)); Amr Zaky, University of Santa Clara (Chapter 5 and [Appendix B](#)).

Jichuan Chang, Junwhan Ahn, Rama Govindaraju, and Milad Hashemi assisted in the development and testing of the case studies and exercises for [Chapter 6](#).

Additional Material

John Nickolls, Steve Keckler, and Michael Toksvig of NVIDIA ([Chapter 4](#) NVIDIA GPUs); Victor Lee, Intel ([Chapter 4](#) comparison of Core i7 and GPU); John Shalf, LBNL ([Chapter 4](#) recent vector architectures); Sam Williams, LBNL (Roofline model for computers in [Chapter 4](#)); Steve Blackburn of Australian National University and Kathryn McKinley of University of Texas at Austin (Intel performance and power measurements in [Chapter 5](#)); Luiz Barroso, Urs Hölzle, Jimmy Clidaris, Bob Felderman, and Chris Johnson of Google (the Google WSC in [Chapter 6](#)); James Hamilton of Amazon Web Services (power distribution and cost model in [Chapter 6](#)).

Jason D. Bakos of the University of South Carolina updated the lecture slides for this edition.

This book could not have been published without a publisher, of course. We wish to thank all the Morgan Kaufmann/Elsevier staff for their efforts and support. For this fifth edition, we particularly want to thank our editors Nate McFadden and Steve Merken, who coordinated surveys, development of the case studies and exercises, manuscript reviews, and the updating of the appendices.

We must also thank our university staff, Margaret Rowland and Roxana Infante, for countless express mailings, as well as for holding down the fort at Stanford and Berkeley while we worked on the book.

Our final thanks go to our wives for their suffering through increasingly early mornings of reading, thinking, and writing.

Fundamentals of Quantitative Design and Analysis

An iPod, a phone, an Internet mobile communicator... these are NOT three separate devices! And we are calling it iPhone! Today Apple is going to reinvent the phone. And here it is.

Steve Jobs, January 9, 2007

New information and communications technologies, in particular high-speed Internet, are changing the way companies do business, transforming public service delivery and democratizing innovation. With 10 percent increase in high speed Internet connections, economic growth increases by 1.3 percent.

The World Bank, July 28, 2009

1.1

Introduction

Computer technology has made incredible progress in the roughly 70 years since the first general-purpose electronic computer was created. Today, less than \$500 will purchase a cell phone that has as much performance as the world's fastest computer bought in 1993 for \$50 million. This rapid improvement has come both from advances in the technology used to build computers and from innovations in computer design.

Although technological improvements historically have been fairly steady, progress arising from better computer architectures has been much less consistent. During the first 25 years of electronic computers, both forces made a major contribution, delivering performance improvement of about 25% per year. The late 1970s saw the emergence of the microprocessor. The ability of the microprocessor to ride the improvements in integrated circuit technology led to a higher rate of performance improvement—roughly 35% growth per year.

This growth rate, combined with the cost advantages of a mass-produced microprocessor, led to an increasing fraction of the computer business being based on microprocessors. In addition, two significant changes in the computer marketplace made it easier than ever before to succeed commercially with a new architecture. First, the virtual elimination of assembly language programming reduced the need for object-code compatibility. Second, the creation of standardized, vendor-independent operating systems, such as UNIX and its clone, Linux, lowered the cost and risk of bringing out a new architecture.

These changes made it possible to develop successfully a new set of architectures with simpler instructions, called RISC (Reduced Instruction Set Computer) architectures, in the early 1980s. The RISC-based machines focused the attention of designers on two critical performance techniques, the exploitation of *instruction-level parallelism* (initially through pipelining and later through multiple instruction issue) and the use of caches (initially in simple forms and later using more sophisticated organizations and optimizations).

The RISC-based computers raised the performance bar, forcing prior architectures to keep up or disappear. The Digital Equipment Vax could not, and so it was replaced by a RISC architecture. Intel rose to the challenge, primarily by translating 80x86 instructions into RISC-like instructions internally, allowing it to adopt many of the innovations first pioneered in the RISC designs. As transistor counts soared in the late 1990s, the hardware overhead of translating the more complex x86 architecture became negligible. In low-end applications, such as cell phones, the cost in power and silicon area of the x86-translation overhead helped lead to a RISC architecture, ARM, becoming dominant.

Figure 1.1 shows that the combination of architectural and organizational enhancements led to 17 years of sustained growth in performance at an annual rate of over 50%—a rate that is unprecedented in the computer industry.

The effect of this dramatic growth rate during the 20th century was fourfold. First, it has significantly enhanced the capability available to computer users. For many applications, the highest-performance microprocessors outperformed the supercomputer of less than 20 years earlier.

Figure 1.1 Growth in processor performance over 40 years. This chart plots program performance relative to the VAX 11/780 as measured by the SPEC integer benchmarks (see [Section 1.8](#)). Prior to the mid-1980s, growth in processor performance was largely technology-driven and averaged about 22% per year, or doubling performance every 3.5 years. The increase in growth to about 52% starting in 1986, or doubling every 2 years, is attributable to more advanced architectural and organizational ideas typified in RISC architectures. By 2003 this growth led to a difference in performance of an approximate factor of 25 versus the performance that would have occurred if it had continued at the 22% rate. In 2003 the limits of power due to the end of Dennard scaling and the available instruction-level parallelism slowed uniprocessor performance to 23% per year until 2011, or doubling every 3.5 years. (The fastest SPECintbase performance since 2007 has had automatic parallelization turned on, so uniprocessor speed is harder to gauge. These results are limited to single-chip systems with usually four cores per chip.) From 2011 to 2015, the annual improvement was less than 12%, or doubling every 8 years in part due to the limits of parallelism of Amdahl's Law. Since 2015, with the end of Moore's Law, improvement has been just 3.5% per year, or doubling every 20 years! Performance for floating-point-oriented calculations follows the same trends, but typically has 1% to 2% higher annual growth in each shaded region. [Figure 1.11](#) on page 27 shows the improvement in clock rates for these same eras. Because SPEC has changed over the years, performance of newer machines is estimated by a scaling factor that relates the performance for different versions of SPEC: SPEC89, SPEC92, SPEC95, SPEC2000, and SPEC2006. There are too few results for SPEC2017 to plot yet.

Second, this dramatic improvement in cost-performance led to new classes of computers. Personal computers and workstations emerged in the 1980s with the availability of the microprocessor. The past decade saw the rise of smart cell phones and tablet computers, which many people are using as their primary computing platforms instead of PCs. These mobile client devices are increasingly using the Internet to access warehouses containing 100,000 servers, which are being designed as if they were a single gigantic computer.

Third, improvement of semiconductor manufacturing as predicted by Moore's law has led to the dominance of microprocessor-based computers across the entire range of computer design. Minicomputers, which were traditionally made from off-the-shelf logic or from gate arrays, were replaced by servers made by using microprocessors. Even mainframe computers and high-performance supercomputers are all collections of microprocessors.

The preceding hardware innovations led to a renaissance in computer design, which emphasized both architectural innovation and efficient use of technology improvements. This rate of growth compounded so that by 2003, high-performance microprocessors were 7.5 times as fast as what would have been obtained by relying solely on technology, including improved circuit design, that is, 52% per year versus 35% per year.

This hardware renaissance led to the fourth impact, which was on software development. This 50,000-fold performance improvement since 1978 (see [Figure 1.1](#)) allowed modern programmers to trade performance for productivity. In place of performance-oriented languages like C and C++, much more programming today is done in managed programming languages like Java and Scala. Moreover, scripting languages like JavaScript and Python, which are even more productive, are gaining in popularity along with programming frameworks like AngularJS and Django. To maintain productivity and try to close the performance gap, interpreters with just-in-time compilers and trace-based compiling are replacing the traditional compiler and linker of the past. Software deployment is changing as well, with Software as a Service (SaaS) used over the Internet replacing shrink-wrapped software that must be installed and run on a local computer.

The nature of applications is also changing. Speech, sound, images, and video are becoming increasingly important, along with predictable response time that is so critical to the user experience. An inspiring example is Google Translate. This application lets you hold up your cell phone to point its camera at an object, and the image is sent wirelessly over the Internet to a warehouse-scale computer (WSC) that recognizes the text in the photo and translates it into your native language. You can also speak into it, and it will translate what you said into audio output in another language. It translates text in 90 languages and voice in 15 languages.

Alas, [Figure 1.1](#) also shows that this 17-year hardware renaissance is over. The fundamental reason is that two characteristics of semiconductor processes that were true for decades no longer hold.

In 1974 Robert Dennard observed that power density was constant for a given area of silicon even as you increased the number of transistors because of smaller dimensions of each transistor. Remarkably, transistors could go faster but use less

power. *Dennard scaling* ended around 2004 because current and voltage couldn't keep dropping and still maintain the dependability of integrated circuits.

This change forced the microprocessor industry to use multiple efficient processors or cores instead of a single inefficient processor. Indeed, in 2004 Intel canceled its high-performance uniprocessor projects and joined others in declaring that the road to higher performance would be via multiple processors per chip rather than via faster uniprocessors. This milestone signaled a historic switch from relying solely on instruction-level parallelism (ILP), the primary focus of the first three editions of this book, to *data-level parallelism* (DLP) and *thread-level parallelism* (TLP), which were featured in the fourth edition and expanded in the fifth edition. The fifth edition also added WSCs and *request-level parallelism* (RLP), which is expanded in this edition. Whereas the compiler and hardware conspire to exploit ILP implicitly without the programmer's attention, DLP, TLP, and RLP are explicitly parallel, requiring the restructuring of the application so that it can exploit explicit parallelism. In some instances, this is easy; in many, it is a major new burden for programmers.

Amdahl's Law (Section 1.9) prescribes practical limits to the number of useful cores per chip. If 10% of the task is serial, then the maximum performance benefit from parallelism is 10 no matter how many cores you put on the chip.

The second observation that ended recently is *Moore's Law*. In 1965 Gordon Moore famously predicted that the number of transistors per chip would double every year, which was amended in 1975 to every two years. That prediction lasted for about 50 years, but no longer holds. For example, in the 2010 edition of this book, the most recent Intel microprocessor had 1,170,000,000 transistors. If Moore's Law had continued, we could have expected microprocessors in 2016 to have 18,720,000,000 transistors. Instead, the equivalent Intel microprocessor has just 1,750,000,000 transistors, or off by a factor of 10 from what Moore's Law would have predicted.

The combination of

- transistors no longer getting much better because of the slowing of Moore's Law and the end of Dennard scaling,
- the unchanging power budgets for microprocessors,
- the replacement of the single power-hungry processor with several energy-efficient processors, and
- the limits to multiprocessing to achieve Amdahl's Law

caused improvements in processor performance to slow down, that is, to *double every 20 years*, rather than every 1.5 years as it did between 1986 and 2003 (see Figure 1.1).

The only path left to improve energy-performance-cost is specialization. Future microprocessors will include several domain-specific cores that perform only one class of computations well, but they do so remarkably better than general-purpose cores. The new Chapter 7 in this edition introduces *domain-specific architectures*.

This text is about the architectural ideas and accompanying compiler improvements that made the incredible growth rate possible over the past century, the reasons for the dramatic change, and the challenges and initial promising approaches to architectural ideas, compilers, and interpreters for the 21st century. At the core is a quantitative approach to computer design and analysis that uses empirical observations of programs, experimentation, and simulation as its tools. It is this style and approach to computer design that is reflected in this text. The purpose of this chapter is to lay the quantitative foundation on which the following chapters and appendices are based.

This book was written not only to explain this design style but also to stimulate you to contribute to this progress. We believe this approach will serve the computers of the future just as it worked for the implicitly parallel computers of the past.

1.2

Classes of Computers

These changes have set the stage for a dramatic change in how we view computing, computing applications, and the computer markets in this new century. Not since the creation of the personal computer have we seen such striking changes in the way computers appear and in how they are used. These changes in computer use have led to five diverse computing markets, each characterized by different applications, requirements, and computing technologies. [Figure 1.2](#) summarizes these mainstream classes of computing environments and their important characteristics.

Internet of Things/Embedded Computers

Embedded computers are found in everyday machines: microwaves, washing machines, most printers, networking switches, and all automobiles. The phrase

Feature	Personal mobile device (PMD)	Desktop	Server	Clusters/warehouse-scale computer	Internet of things/embedded
Price of system	\$100–\$1000	\$300–\$2500	\$5000–\$10,000,000	\$100,000–\$200,000,000	\$10–\$100,000
Price of microprocessor	\$10–\$100	\$50–\$500	\$200–\$2000	\$50–\$250	\$0.01–\$100
Critical system design issues	Cost, energy, media performance, responsiveness	Price-performance, energy, graphics performance	Throughput, availability, scalability, energy	Price-performance, throughput, energy proportionality	Price, energy, application-specific performance

Figure 1.2 A summary of the five mainstream computing classes and their system characteristics. Sales in 2015 included about 1.6 billion PMDs (90% cell phones), 275 million desktop PCs, and 15 million servers. The total number of embedded processors sold was nearly 19 billion. In total, 14.8 billion ARM-technology-based chips were shipped in 2015. Note the wide range in system price for servers and embedded systems, which go from USB keys to network routers. For servers, this range arises from the need for very large-scale multiprocessor systems for high-end transaction processing.

Internet of Things (IoT) refers to embedded computers that are connected to the Internet, typically wirelessly. When augmented with sensors and actuators, IoT devices collect useful data and interact with the physical world, leading to a wide variety of “smart” applications, such as smart watches, smart thermostats, smart speakers, smart cars, smart homes, smart grids, and smart cities.

Embedded computers have the widest spread of processing power and cost. They include 8-bit to 32-bit processors that may cost one penny, and high-end 64-bit processors for cars and network switches that cost \$100. Although the range of computing power in the embedded computing market is very large, price is a key factor in the design of computers for this space. Performance requirements do exist, of course, but the primary goal often meets the performance need at a minimum price, rather than achieving more performance at a higher price. The projections for the number of IoT devices in 2020 range from 20 to 50 billion.

Most of this book applies to the design, use, and performance of embedded processors, whether they are off-the-shelf microprocessors or microprocessor cores that will be assembled with other special-purpose hardware.

Unfortunately, the data that drive the quantitative design and evaluation of other classes of computers have not yet been extended successfully to embedded computing (see the challenges with EEMBC, for example, in [Section 1.8](#)). Hence we are left for now with qualitative descriptions, which do not fit well with the rest of the book. As a result, the embedded material is concentrated in Appendix E. We believe a separate appendix improves the flow of ideas in the text while allowing readers to see how the differing requirements affect embedded computing.

Personal Mobile Device

Personal mobile device (PMD) is the term we apply to a collection of wireless devices with multimedia user interfaces such as cell phones, tablet computers, and so on. Cost is a prime concern given the consumer price for the whole product is a few hundred dollars. Although the emphasis on energy efficiency is frequently driven by the use of batteries, the need to use less expensive packaging—plastic versus ceramic—and the absence of a fan for cooling also limit total power consumption. We examine the issue of energy and power in more detail in [Section 1.5](#). Applications on PMDs are often web-based and media-oriented, like the previously mentioned Google Translate example. Energy and size requirements lead to use of Flash memory for storage ([Chapter 2](#)) instead of magnetic disks.

The processors in a PMD are often considered embedded computers, but we are keeping them as a separate category because PMDs are platforms that can run externally developed software, and they share many of the characteristics of desktop computers. Other embedded devices are more limited in hardware and software sophistication. We use the ability to run third-party software as the dividing line between nonembedded and embedded computers.

Responsiveness and predictability are key characteristics for media applications. A *real-time performance* requirement means a segment of the application has an absolute maximum execution time. For example, in playing a video on a

PMD, the time to process each video frame is limited, since the processor must accept and process the next frame shortly. In some applications, a more nuanced requirement exists: the average time for a particular task is constrained as well as the number of instances when some maximum time is exceeded. Such approaches—sometimes called *soft real-time*—arise when it is possible to miss the time constraint on an event occasionally, as long as not too many are missed. Real-time performance tends to be highly application-dependent.

Other key characteristics in many PMD applications are the need to minimize memory and the need to use energy efficiently. Energy efficiency is driven by both battery power and heat dissipation. The memory can be a substantial portion of the system cost, and it is important to optimize memory size in such cases. The importance of memory size translates to an emphasis on code size, since data size is dictated by the application.

Desktop Computing

The first, and possibly still the largest market in dollar terms, is desktop computing. Desktop computing spans from low-end netbooks that sell for under \$300 to high-end, heavily configured workstations that may sell for \$2500. Since 2008, more than half of the desktop computers made each year have been battery operated laptop computers. Desktop computing sales are declining.

Throughout this range in price and capability, the desktop market tends to be driven to optimize *price-performance*. This combination of performance (measured primarily in terms of compute performance and graphics performance) and price of a system is what matters most to customers in this market, and hence to computer designers. As a result, the newest, highest-performance microprocessors and cost-reduced microprocessors often appear first in desktop systems (see [Section 1.6](#) for a discussion of the issues affecting the cost of computers).

Desktop computing also tends to be reasonably well characterized in terms of applications and benchmarking, though the increasing use of web-centric, interactive applications poses new challenges in performance evaluation.

Servers

As the shift to desktop computing occurred in the 1980s, the role of servers grew to provide larger-scale and more reliable file and computing services. Such servers have become the backbone of large-scale enterprise computing, replacing the traditional mainframe.

For servers, different characteristics are important. First, availability is critical. (We discuss availability in [Section 1.7](#).) Consider the servers running ATM machines for banks or airline reservation systems. Failure of such server systems is far more catastrophic than failure of a single desktop, since these servers must operate seven days a week, 24 hours a day. [Figure 1.3](#) estimates revenue costs of downtime for server applications.

Application	Cost of downtime per hour	Annual losses with downtime of		
		1% (87.6 h/year)	0.5% (43.8 h/year)	0.1% (8.8 h/year)
Brokerage service	\$4,000,000	\$350,400,000	\$175,200,000	\$35,000,000
Energy	\$1,750,000	\$153,300,000	\$76,700,000	\$15,300,000
Telecom	\$1,250,000	\$109,500,000	\$54,800,000	\$11,000,000
Manufacturing	\$1,000,000	\$87,600,000	\$43,800,000	\$8,800,000
Retail	\$650,000	\$56,900,000	\$28,500,000	\$5,700,000
Health care	\$400,000	\$35,000,000	\$17,500,000	\$3,500,000
Media	\$50,000	\$4,400,000	\$2,200,000	\$400,000

Figure 1.3 Costs rounded to nearest \$100,000 of an unavailable system are shown by analyzing the cost of downtime (in terms of immediately lost revenue), assuming three different levels of availability, and that downtime is distributed uniformly. These data are from [Landstrom \(2014\)](#) and were collected and analyzed by Contingency Planning Research.

A second key feature of server systems is scalability. Server systems often grow in response to an increasing demand for the services they support or an expansion in functional requirements. Thus the ability to scale up the computing capacity, the memory, the storage, and the I/O bandwidth of a server is crucial.

Finally, servers are designed for efficient throughput. That is, the overall performance of the server—in terms of transactions per minute or web pages served per second—is what is crucial. Responsiveness to an individual request remains important, but overall efficiency and cost-effectiveness, as determined by how many requests can be handled in a unit time, are the key metrics for most servers. We return to the issue of assessing performance for different types of computing environments in [Section 1.8](#).

Clusters/Warehouse-Scale Computers

The growth of Software as a Service (SaaS) for applications like search, social networking, video viewing and sharing, multiplayer games, online shopping, and so on has led to the growth of a class of computers called *clusters*. Clusters are collections of desktop computers or servers connected by local area networks to act as a single larger computer. Each node runs its own operating system, and nodes communicate using a networking protocol. WSCs are the largest of the clusters, in that they are designed so that tens of thousands of servers can act as one. [Chapter 6](#) describes this class of extremely large computers.

Price-performance and power are critical to WSCs since they are so large. As [Chapter 6](#) explains, the majority of the cost of a warehouse is associated with power and cooling of the computers inside the warehouse. The annual amortized computers themselves and the networking gear cost for a WSC is \$40 million, because they are usually replaced every few years. When you are buying that

much computing, you need to buy wisely, because a 10% improvement in price-performance means an annual savings of \$4 million (10% of \$40 million) per WSC; a company like Amazon might have 100 WSCs!

WSCs are related to servers in that availability is critical. For example, Amazon.com had \$136 billion in sales in 2016. As there are about 8800 hours in a year, the average revenue per hour was about \$15 million. During a peak hour for Christmas shopping, the potential loss would be many times higher. As [Chapter 6](#) explains, the difference between WSCs and servers is that WSCs use redundant, inexpensive components as the building blocks, relying on a software layer to catch and isolate the many failures that will happen with computing at this scale to deliver the availability needed for such applications. Note that scalability for a WSC is handled by the local area network connecting the computers and not by integrated computer hardware, as in the case of servers.

Supercomputers are related to WSCs in that they are equally expensive, costing hundreds of millions of dollars, but supercomputers differ by emphasizing floating-point performance and by running large, communication-intensive batch programs that can run for weeks at a time. In contrast, WSCs emphasize interactive applications, large-scale storage, dependability, and high Internet bandwidth.

Classes of Parallelism and Parallel Architectures

Parallelism at multiple levels is now the driving force of computer design across all four classes of computers, with energy and cost being the primary constraints. There are basically two kinds of parallelism in applications:

1. *Data-level parallelism (DLP)* arises because there are many data items that can be operated on at the same time.
2. *Task-level parallelism (TLP)* arises because tasks of work are created that can operate independently and largely in parallel.

Computer hardware in turn can exploit these two kinds of application parallelism in four major ways:

1. *Instruction-level parallelism* exploits data-level parallelism at modest levels with compiler help using ideas like pipelining and at medium levels using ideas like speculative execution.
2. *Vector architectures, graphic processor units (GPUs), and multimedia instruction sets* exploit data-level parallelism by applying a single instruction to a collection of data in parallel.
3. *Thread-level parallelism* exploits either data-level parallelism or task-level parallelism in a tightly coupled hardware model that allows for interaction between parallel threads.
4. *Request-level parallelism* exploits parallelism among largely decoupled tasks specified by the programmer or the operating system.

When [Flynn \(1966\)](#) studied the parallel computing efforts in the 1960s, he found a simple classification whose abbreviations we still use today. They target data-level parallelism and task-level parallelism. He looked at the parallelism in the instruction and data streams called for by the instructions at the most constrained component of the multiprocessor and placed all computers in one of four categories:

1. *Single instruction stream, single data stream (SISD)*—This category is the uniprocessor. The programmer thinks of it as the standard sequential computer, but it can exploit ILP. [Chapter 3](#) covers SISD architectures that use ILP techniques such as superscalar and speculative execution.
2. *Single instruction stream, multiple data streams (SIMD)*—The same instruction is executed by multiple processors using different data streams. SIMD computers exploit *data-level parallelism* by applying the same operations to multiple items of data in parallel. Each processor has its own data memory (hence, the MD of SIMD), but there is a single instruction memory and control processor, which fetches and dispatches instructions. [Chapter 4](#) covers DLP and three different architectures that exploit it: vector architectures, multimedia extensions to standard instruction sets, and GPUs.
3. *Multiple instruction streams, single data stream (MISD)*—No commercial multiprocessor of this type has been built to date, but it rounds out this simple classification.
4. *Multiple instruction streams, multiple data streams (MIMD)*—Each processor fetches its own instructions and operates on its own data, and it targets task-level parallelism. In general, MIMD is more flexible than SIMD and thus more generally applicable, but it is inherently more expensive than SIMD. For example, MIMD computers can also exploit data-level parallelism, although the overhead is likely to be higher than would be seen in an SIMD computer. This overhead means that grain size must be sufficiently large to exploit the parallelism efficiently. [Chapter 5](#) covers tightly coupled MIMD architectures, which exploit *thread-level parallelism* because multiple cooperating threads operate in parallel. [Chapter 6](#) covers loosely coupled MIMD architectures—specifically, *clusters* and *warehouse-scale computers*—that exploit *request-level parallelism*, where many independent tasks can proceed in parallel naturally with little need for communication or synchronization.

This taxonomy is a coarse model, as many parallel processors are hybrids of the SISD, SIMD, and MIMD classes. Nonetheless, it is useful to put a framework on the design space for the computers we will see in this book.

The task the computer designer faces is a complex one: determine what attributes are important for a new computer, then design a computer to maximize

performance and energy efficiency while staying within cost, power, and availability constraints. This task has many aspects, including instruction set design, functional organization, logic design, and implementation. The implementation may encompass integrated circuit design, packaging, power, and cooling. Optimizing the design requires familiarity with a very wide range of technologies, from compilers and operating systems to logic design and packaging.

A few decades ago, the term *computer architecture* generally referred to only instruction set design. Other aspects of computer design were called *implementation*, often insinuating that implementation is uninteresting or less challenging.

We believe this view is incorrect. The architect's or designer's job is much more than instruction set design, and the technical hurdles in the other aspects of the project are likely more challenging than those encountered in instruction set design. We'll quickly review instruction set architecture before describing the larger challenges for the computer architect.

Instruction Set Architecture: The Myopic View of Computer Architecture

We use the term *instruction set architecture* (ISA) to refer to the actual programmer-visible instruction set in this book. The ISA serves as the boundary between the software and hardware. This quick review of ISA will use examples from 80x86, ARMv8, and RISC-V to illustrate the seven dimensions of an ISA. The most popular RISC processors come from ARM (Advanced RISC Machine), which were in 14.8 billion chips shipped in 2015, or roughly 50 times as many chips that shipped with 80x86 processors. Appendices A and K give more details on the three ISAs.

RISC-V (“RISC Five”) is a modern RISC instruction set developed at the University of California, Berkeley, which was made free and openly adoptable in response to requests from industry. In addition to a full software stack (compilers, operating systems, and simulators), there are several RISC-V implementations freely available for use in custom chips or in field-programmable gate arrays. Developed 30 years after the first RISC instruction sets, RISC-V inherits its ancestors' good ideas—a large set of registers, easy-to-pipeline instructions, and a lean set of operations—while avoiding their omissions or mistakes. It is a free and open, elegant example of the RISC architectures mentioned earlier, which is why more than 60 companies have joined the RISC-V foundation, including AMD, Google, HP Enterprise, IBM, Microsoft, Nvidia, Qualcomm, Samsung, and Western Digital. We use the integer core ISA of RISC-V as the example ISA in this book.

1. *Class of ISA*—Nearly all ISAs today are classified as general-purpose register architectures, where the operands are either registers or memory locations. The 80x86 has 16 general-purpose registers and 16 that can hold floating-point data, while RISC-V has 32 general-purpose and 32 floating-point registers (see [Figure 1.4](#)). The two popular versions of this class are *register-memory* ISAs,

Register	Name	Use	Saver
x0	zero	The constant value 0	N.A.
x1	ra	Return address	Caller
x2	sp	Stack pointer	Callee
x3	gp	Global pointer	—
x4	tp	Thread pointer	—
x5–x7	t0–t2	Temporaries	Caller
x8	s0/fp	Saved register/frame pointer	Callee
x9	s1	Saved register	Callee
x10–x11	a0–a1	Function arguments/return values	Caller
x12–x17	a2–a7	Function arguments	Caller
x18–x27	s2–s11	Saved registers	Callee
x28–x31	t3–t6	Temporaries	Caller
f0–f7	ft0–ft7	FP temporaries	Caller
f8–f9	fs0–fs1	FP saved registers	Callee
f10–f11	fa0–fa1	FP function arguments/return values	Caller
f12–f17	fa2–fa7	FP function arguments	Caller
f18–f27	fs2–fs11	FP saved registers	Callee
f28–f31	ft8–ft11	FP temporaries	Caller

Figure 1.4 RISC-V registers, names, usage, and calling conventions. In addition to the 32 general-purpose registers (x0–x31), RISC-V has 32 floating-point registers (f0–f31) that can hold either a 32-bit single-precision number or a 64-bit double-precision number. The registers that are preserved across a procedure call are labeled “Callee” saved.

such as the 80x86, which can access memory as part of many instructions, and *load-store* ISAs, such as ARMv8 and RISC-V, which can access memory only with load or store instructions. All ISAs announced since 1985 are load-store.

2. *Memory addressing*—Virtually all desktop and server computers, including the 80x86, ARMv8, and RISC-V, use byte addressing to access memory operands. Some architectures, like ARMv8, require that objects must be *aligned*. An access to an object of size s bytes at byte address A is aligned if $A \bmod s = 0$. (See Figure A.5 on page A-8.) The 80x86 and RISC-V do not require alignment, but accesses are generally faster if operands are aligned.
3. *Addressing modes*—In addition to specifying registers and constant operands, addressing modes specify the address of a memory object. RISC-V addressing modes are Register, Immediate (for constants), and Displacement, where a constant offset is added to a register to form the memory address. The 80x86 supports those three modes, plus three variations of displacement: no register (absolute), two registers (based indexed with displacement), and two registers

where one register is multiplied by the size of the operand in bytes (based with scaled index and displacement). It has more like the last three modes, minus the displacement field, plus register indirect, indexed, and based with scaled index. ARMv8 has the three RISC-V addressing modes plus PC-relative addressing, the sum of two registers, and the sum of two registers where one register is multiplied by the size of the operand in bytes. It also has autoincrement and autodecrement addressing, where the calculated address replaces the contents of one of the registers used in forming the address.

4. *Types and sizes of operands*—Like most ISAs, 80x86, ARMv8, and RISC-V support operand sizes of 8-bit (ASCII character), 16-bit (Unicode character or half word), 32-bit (integer or word), 64-bit (double word or long integer), and IEEE 754 floating point in 32-bit (single precision) and 64-bit (double precision). The 80x86 also supports 80-bit floating point (extended double precision).
5. *Operations*—The general categories of operations are data transfer, arithmetic logical, control (discussed next), and floating point. RISC-V is a simple and easy-to-pipeline instruction set architecture, and it is representative of the RISC architectures being used in 2017. [Figure 1.5](#) summarizes the integer RISC-V ISA, and [Figure 1.6](#) lists the floating-point ISA. The 80x86 has a much richer and larger set of operations (see Appendix K).
6. *Control flow instructions*—Virtually all ISAs, including these three, support conditional branches, unconditional jumps, procedure calls, and returns. All three use PC-relative addressing, where the branch address is specified by an address field that is added to the PC. There are some small differences. RISC-V conditional branches (BE, BNE, etc.) test the contents of registers, and the 80x86 and ARMv8 branches test condition code bits set as side effects of arithmetic/logic operations. The ARMv8 and RISC-V procedure call places the return address in a register, whereas the 80x86 call (CALLF) places the return address on a stack in memory.
7. *Encoding an ISA*—There are two basic choices on encoding: *fixed length* and *variable length*. All ARMv8 and RISC-V instructions are 32 bits long, which simplifies instruction decoding. [Figure 1.7](#) shows the RISC-V instruction formats. The 80x86 encoding is variable length, ranging from 1 to 18 bytes. Variable-length instructions can take less space than fixed-length instructions, so a program compiled for the 80x86 is usually smaller than the same program compiled for RISC-V. Note that choices mentioned previously will affect how the instructions are encoded into a binary representation. For example, the number of registers and the number of addressing modes both have a significant impact on the size of instructions, because the register field and addressing mode field can appear many times in a single instruction. (Note that ARMv8 and RISC-V later offered extensions, called Thumb-2 and RV64IC, that provide a mix of 16-bit and 32-bit length instructions, respectively, to reduce program size. Code size for these compact versions of RISC architectures are smaller than that of the 80x86. See Appendix K.)

Instruction type/opcode	Instruction meaning
<i>Data transfers</i>	<i>Move data between registers and memory, or between the integer and FP or special registers; only memory address mode is 12-bit displacement + contents of a GPR</i>
lb, lbu, sb	Load byte, load byte unsigned, store byte (to/from integer registers)
lh, lhu, sh	Load half word, load half word unsigned, store half word (to/from integer registers)
lw, lwu, sw	Load word, load word unsigned, store word (to/from integer registers)
ld, sd	Load double word, store double word (to/from integer registers)
flw, fld, fsw, fsd	Load SP float, load DP float, store SP float, store DP float
fmv. __.x, fmv.x. __	Copy from/to integer register to/from floating-point register; “__” = S for single-precision, D for double-precision
csrrw, csrrwi, csrrs, csrrsi, csrrc, csrrci	Read counters and write status registers, which include counters: clock cycles, time, instructions retired
<i>Arithmetic/logical</i>	<i>Operations on integer or logical data in GPRs</i>
add, addi, addw, addiw	Add, add immediate (all immediates are 12 bits), add 32-bits only & sign-extend to 64 bits, add immediate 32-bits only
sub, subw	Subtract, subtract 32-bits only
mul, mulw, mulh, mulhsu, mulhu	Multiply, multiply 32-bits only, multiply upper half, multiply upper half signed-unsigned, multiply upper half unsigned
div, divu, rem, remu	Divide, divide unsigned, remainder, remainder unsigned
divw, divuw, remw, remuw	Divide and remainder: as previously, but divide only lower 32-bits, producing 32-bit sign-extended result
and, andi	And, and immediate
or, ori, xor, xori	Or, or immediate, exclusive or, exclusive or immediate
lui	Load upper immediate; loads bits 31-12 of register with immediate, then sign-extends
auipc	Adds immediate in bits 31-12 with zeros in lower bits to PC; used with JALR to transfer control to any 32-bit address
sll, slli, srl, srli, sra, srai	Shifts: shift left logical, right logical, right arithmetic; both variable and immediate forms
sllw, slliw, srlw, srliw, saw, saiw	Shifts: as previously, but shift lower 32-bits, producing 32-bit sign-extended result
slt, slti, sltu, sltiu	Set less than, set less than immediate, signed and unsigned
<i>Control</i>	<i>Conditional branches and jumps; PC-relative or through register</i>
beq, bne, blt, bge, bltu, bgeu	Branch GPR equal/not equal; less than; greater than or equal, signed and unsigned
jal, jalr	Jump and link: save PC + 4, target is PC-relative (JAL) or a register (JALR); if specify x0 as destination register, then acts as a simple jump
ecall	Make a request to the supporting execution environment, which is usually an OS
ebreak	Debuggers used to cause control to be transferred back to a debugging environment
fence, fence.i	Synchronize threads to guarantee ordering of memory accesses; synchronize instructions and data for stores to instruction memory

Figure 1.5 Subset of the instructions in RISC-V. RISC-V has a base set of instructions (R64I) and offers optional extensions: multiply-divide (RVM), single-precision floating point (RVF), double-precision floating point (RVD). This figure includes RVM and the next one shows RVF and RVD. [Appendix A](#) gives much more detail on RISC-V.

Instruction type/opcode	Instruction meaning
<i>Floating point</i>	<i>FP operations on DP and SP formats</i>
fadd.d, fadd.s	Add DP, SP numbers
fsub.d, fsub.s	Subtract DP, SP numbers
fmul.d, fmul.s	Multiply DP, SP floating point
fmadd.d, fmadd.s, fnmadd.d, fnmadd.s	Multiply-add DP, SP numbers; negative multiply-add DP, SP numbers
fmsub.d, fmsub.s, fnmsub.d, fnmsub.s	Multiply-sub DP, SP numbers; negative multiply-sub DP, SP numbers
fdiv.d, fdiv.s	Divide DP, SP floating point
fsqrt.d, fsqrt.s	Square root DP, SP floating point
fmax.d, fmax.s, fmin.d, fmin.s	Maximum and minimum DP, SP floating point
fcvt.____, fcvt.____u, fcvt._u._	Convert instructions: FCVT.x.y converts from type x to type y, where x and y are L (64-bit integer), W (32-bit integer), D (DP), or S (SP). Integers can be unsigned (U)
feq.____, flt.____, fle.____	Floating-point compare between floating-point registers and record the Boolean result in integer register; “_” = S for single-precision, D for double-precision
fclass.d, fclass.s	Writes to integer register a 10-bit mask that indicates the class of the floating-point number ($-\infty$, $+\infty$, -0 , $+0$, NaN, ...)
fsgnj.____, fsgnjn.____, fsgnjx.____	Sign-injection instructions that changes only the sign bit: copy sign bit from other source, the opposite of sign bit of other source, XOR of the 2 sign bits

Figure 1.6 Floating point instructions for RISC-V. RISC-V has a base set of instructions (R64I) and offers optional extensions for single-precision floating point (RVF) and double-precision floating point (RVD). SP=single precision; DP=double precision.

Figure 1.7 The base RISC-V instruction set architecture formats. All instructions are 32 bits long. The R format is for integer register-to-register operations, such as ADD, SUB, and so on. The I format is for loads and immediate operations, such as LD and ADDI. The B format is for branches and the J format is for jumps and link. The S format is for stores. Having a separate format for stores allows the three register specifiers (rd, rs1, rs2) to always be in the same location in all formats. The U format is for the wide immediate instructions (LUI, AUIPC).

The other challenges facing the computer architect beyond ISA design are particularly acute at the present, when the differences among instruction sets are small and when there are distinct application areas. Therefore, starting with the fourth edition of this book, beyond this quick review, the bulk of the instruction set material is found in the appendices (see Appendices A and K).

Genuine Computer Architecture: Designing the Organization and Hardware to Meet Goals and Functional Requirements

The implementation of a computer has two components: organization and hardware. The term *organization* includes the high-level aspects of a computer's design, such as the memory system, the memory interconnect, and the design of the internal processor or CPU (central processing unit—where arithmetic, logic, branching, and data transfer are implemented). The term *microarchitecture* is also used instead of organization. For example, two processors with the same instruction set architectures but different organizations are the AMD Opteron and the Intel Core i7. Both processors implement the 80x86 instruction set, but they have very different pipeline and cache organizations.

The switch to multiple processors per microprocessor led to the term *core* also being used for processors. Instead of saying multiprocessor microprocessor, the term *multicore* caught on. Given that virtually all chips have multiple processors, the term central processing unit, or CPU, is fading in popularity.

Hardware refers to the specifics of a computer, including the detailed logic design and the packaging technology of the computer. Often a line of computers contains computers with identical instruction set architectures and very similar organizations, but they differ in the detailed hardware implementation. For example, the Intel Core i7 (see [Chapter 3](#)) and the Intel Xeon E7 (see [Chapter 5](#)) are nearly identical but offer different clock rates and different memory systems, making the Xeon E7 more effective for server computers.

In this book, the word *architecture* covers all three aspects of computer design—instruction set architecture, organization or microarchitecture, and hardware.

Computer architects must design a computer to meet functional requirements as well as price, power, performance, and availability goals. [Figure 1.8](#) summarizes requirements to consider in designing a new computer. Often, architects also must determine what the functional requirements are, which can be a major task. The requirements may be specific features inspired by the market. Application software typically drives the choice of certain functional requirements by determining how the computer will be used. If a large body of software exists for a particular instruction set architecture, the architect may decide that a new computer should implement an existing instruction set. The presence of a large market for a particular class of applications might encourage the designers to incorporate requirements that would make the computer competitive in that market. Later chapters examine many of these requirements and features in depth.

Functional requirements	Typical features required or supported
<i>Application area</i>	<i>Target of computer</i>
Personal mobile device	Real-time performance for a range of tasks, including interactive performance for graphics, video, and audio; energy efficiency (Chapters 2–5 and 7 ; Appendix A)
General-purpose desktop	Balanced performance for a range of tasks, including interactive performance for graphics, video, and audio (Chapters 2–5 ; Appendix A)
Servers	Support for databases and transaction processing; enhancements for reliability and availability; support for scalability (Chapters 2, 5, and 7 ; Appendices A, D, and F)
Clusters/warehouse-scale computers	Throughput performance for many independent tasks; error correction for memory; energy proportionality (Chapters 2, 6, and 7 ; Appendix F)
Internet of things/embedded computing	Often requires special support for graphics or video (or other application-specific extension); power limitations and power control may be required; real-time constraints (Chapters 2, 3, 5, and 7 ; Appendices A and E)
<i>Level of software compatibility</i>	<i>Determines amount of existing software for computer</i>
At programming language	Most flexible for designer; need new compiler (Chapters 3, 5, and 7 ; Appendix A)
Object code or binary compatible	Instruction set architecture is completely defined—little flexibility—but no investment needed in software or porting programs (Appendix A)
<i>Operating system requirements</i>	<i>Necessary features to support chosen OS (Chapter 2; Appendix B)</i>
Size of address space	Very important feature (Chapter 2); may limit applications
Memory management	Required for modern OS; may be paged or segmented (Chapter 2)
Protection	Different OS and application needs: page versus segment; virtual machines (Chapter 2)
<i>Standards</i>	<i>Certain standards may be required by marketplace</i>
Floating point	Format and arithmetic: IEEE 754 standard (Appendix J), special arithmetic for graphics or signal processing
I/O interfaces	For I/O devices: Serial ATA, Serial Attached SCSI, PCI Express (Appendices D and F)
Operating systems	UNIX, Windows, Linux, CISCO IOS
Networks	Support required for different networks: Ethernet, Infiniband (Appendix F)
Programming languages	Languages (ANSI C, C++, Java, Fortran) affect instruction set (Appendix A)

Figure 1.8 Summary of some of the most important functional requirements an architect faces. The left-hand column describes the class of requirement, while the right-hand column gives specific examples. The right-hand column also contains references to chapters and appendices that deal with the specific issues.

Architects must also be aware of important trends in both the technology and the use of computers because such trends affect not only the future cost but also the longevity of an architecture.

1.4

Trends in Technology

If an instruction set architecture is to prevail, it must be designed to survive rapid changes in computer technology. After all, a successful new instruction set

architecture may last decades—for example, the core of the IBM mainframe has been in use for more than 50 years. An architect must plan for technology changes that can increase the lifetime of a successful computer.

To plan for the evolution of a computer, the designer must be aware of rapid changes in implementation technology. Five implementation technologies, which change at a dramatic pace, are critical to modern implementations:

- *Integrated circuit logic technology*—Historically, transistor density increased by about 35% per year, quadrupling somewhat over four years. Increases in die size are less predictable and slower, ranging from 10% to 20% per year. The combined effect was a traditional growth rate in transistor count on a chip of about 40%–55% per year, or doubling every 18–24 months. This trend is popularly known as Moore’s Law. Device speed scales more slowly, as we discuss below. Shockingly, Moore’s Law is no more. The number of devices per chip is still increasing, but at a decelerating rate. Unlike in the Moore’s Law era, we expect the doubling time to be stretched with each new technology generation.
- *Semiconductor DRAM* (dynamic random-access memory)—This technology is the foundation of main memory, and we discuss it in [Chapter 2](#). The growth of DRAM has slowed dramatically, from quadrupling every three years as in the past. The 8-gigabit DRAM was shipping in 2014, but the 16-gigabit DRAM won’t reach that state until 2019, and it looks like there will be no 32-gigabit DRAM ([Kim, 2005](#)). [Chapter 2](#) mentions several other technologies that may replace DRAM when it hits its capacity wall.
- *Semiconductor Flash* (electrically erasable programmable read-only memory)—This nonvolatile semiconductor memory is the standard storage device in PMDs, and its rapidly increasing popularity has fueled its rapid growth rate in capacity. In recent years, the capacity per Flash chip increased by about 50%–60% per year, doubling roughly every 2 years. Currently, Flash memory is 8–10 times cheaper per bit than DRAM. [Chapter 2](#) describes Flash memory.
- *Magnetic disk technology*—Prior to 1990, density increased by about 30% per year, doubling in three years. It rose to 60% per year thereafter, and increased to 100% per year in 1996. Between 2004 and 2011, it dropped back to about 40% per year, or doubled every two years. Recently, disk improvement has slowed to less than 5% per year. One way to increase disk capacity is to add more platters at the same areal density, but there are already seven platters within the one-inch depth of the 3.5-inch form factor disks. There is room for at most one or two more platters. The last hope for real density increase is to use a small laser on each disk read-write head to heat a 30 nm spot to 400°C so that it can be written magnetically before it cools. It is unclear whether Heat Assisted Magnetic Recording can be manufactured economically and reliably, although Seagate announced plans to ship HAMR in limited production in 2018. HAMR is the last chance for continued improvement in areal density of hard disk

drives, which are now 8–10 times cheaper per bit than Flash and 200–300 times cheaper per bit than DRAM. This technology is central to server- and warehouse-scale storage, and we discuss the trends in detail in Appendix D.

- *Network technology*—Network performance depends both on the performance of switches and on the performance of the transmission system. We discuss the trends in networking in Appendix F.

These rapidly changing technologies shape the design of a computer that, with speed and technology enhancements, may have a lifetime of 3–5 years. Key technologies such as Flash change sufficiently that the designer must plan for these changes. Indeed, designers often design for the next technology, knowing that, when a product begins shipping in volume, the following technology may be the most cost-effective or may have performance advantages. Traditionally, cost has decreased at about the rate at which density increases.

Although technology improves continuously, the impact of these increases can be in discrete leaps, as a threshold that allows a new capability is reached. For example, when MOS technology reached a point in the early 1980s where between 25,000 and 50,000 transistors could fit on a single chip, it became possible to build a single-chip, 32-bit microprocessor. By the late 1980s, first-level caches could go on a chip. By eliminating chip crossings within the processor and between the processor and the cache, a dramatic improvement in cost-performance and energy-performance was possible. This design was simply unfeasible until the technology reached a certain point. With multicore microprocessors and increasing numbers of cores each generation, even server computers are increasingly headed toward a single chip for all processors. Such technology thresholds are not rare and have a significant impact on a wide variety of design decisions.

Performance Trends: Bandwidth Over Latency

As we shall see in [Section 1.8](#), *bandwidth* or *throughput* is the total amount of work done in a given time, such as megabytes per second for a disk transfer. In contrast, *latency* or *response time* is the time between the start and the completion of an event, such as milliseconds for a disk access. [Figure 1.9](#) plots the relative improvement in bandwidth and latency for technology milestones for microprocessors, memory, networks, and disks. [Figure 1.10](#) describes the examples and milestones in more detail.

Performance is the primary differentiator for microprocessors and networks, so they have seen the greatest gains: $32,000\text{--}40,000\times$ in bandwidth and $50\text{--}90\times$ in latency. Capacity is generally more important than performance for memory and disks, so capacity has improved more, yet bandwidth advances of $400\text{--}2400\times$ are still much greater than gains in latency of $8\text{--}9\times$.

Clearly, bandwidth has outpaced latency across these technologies and will likely continue to do so. A simple rule of thumb is that bandwidth grows by at least the square of the improvement in latency. Computer designers should plan accordingly.

Figure 1.9 Log-log plot of bandwidth and latency milestones in Figure 1.10 relative to the first milestone. Note that latency improved 8–91 \times , while bandwidth improved about 400–32,000 \times . Except for networking, we note that there were modest improvements in latency and bandwidth in the other three technologies in the six years since the last edition: 0%–23% in latency and 23%–70% in bandwidth. Updated from Patterson, D., 2004. Latency lags bandwidth. *Commun. ACM* 47 (10), 71–75.

Scaling of Transistor Performance and Wires

Integrated circuit processes are characterized by the *feature size*, which is the minimum size of a transistor or a wire in either the x or y dimension. Feature sizes decreased from 10 μm in 1971 to 0.016 μm in 2017; in fact, we have switched units, so production in 2017 is referred to as “16 nm,” and 7 nm chips are underway. Since the transistor count per square millimeter of silicon is determined by the surface area of a transistor, the density of transistors increases quadratically with a linear decrease in feature size.

Figure 1.10 Performance milestones over 25–40 years for microprocessors, memory, networks, and disks. The microprocessor milestones are several generations of IA-32 processors, going from a 16-bit bus, microcoded 80286 to a 64-bit bus, multicore, out-of-order execution, superpipelined Core i7. Memory module milestones go from 16-bit-wide, plain DRAM to 64-bit-wide double data rate version 3 synchronous DRAM. Ethernet advanced from 10 Mbits/s to 400 Gbits/s. Disk milestones are based on rotation speed, improving from 3600 to 15,000 RPM. Each case is best-case bandwidth, and latency is the time for a simple operation assuming no contention. Updated from Patterson, D., 2004. Latency lags bandwidth. *Commun. ACM* 47 (10), 71–75.

The increase in transistor performance, however, is more complex. As feature sizes shrink, devices shrink quadratically in the horizontal dimension and also shrink in the vertical dimension. The shrink in the vertical dimension requires a reduction in operating voltage to maintain correct operation and reliability of the transistors. This combination of scaling factors leads to a complex interrelationship between transistor performance and process feature size. To a first approximation, in the past the transistor performance improved linearly with decreasing feature size.

The fact that transistor count improves quadratically with a linear increase in transistor performance is both the challenge and the opportunity for which computer architects were created! In the early days of microprocessors, the higher rate of improvement in density was used to move quickly from 4-bit, to 8-bit, to 16-bit, to 32-bit, to 64-bit microprocessors. More recently, density improvements have supported the introduction of multiple processors per chip, wider SIMD units, and many of the innovations in speculative execution and caches found in [Chapters 2–5](#).

Although transistors generally improve in performance with decreased feature size, wires in an integrated circuit do not. In particular, the signal delay for a wire increases in proportion to the product of its resistance and capacitance. Of course, as feature size shrinks, wires get shorter, but the resistance and capacitance per unit length get worse. This relationship is complex, since both resistance and capacitance depend on detailed aspects of the process, the geometry of a wire, the loading on a wire, and even the adjacency to other structures. There are occasional process enhancements, such as the introduction of copper, which provide one-time improvements in wire delay.

In general, however, wire delay scales poorly compared to transistor performance, creating additional challenges for the designer. In addition to the power dissipation limit, wire delay has become a major design obstacle for large integrated circuits and is often more critical than transistor switching delay. Larger and larger fractions of the clock cycle have been consumed by the propagation delay of signals on wires, but power now plays an even greater role than wire delay.

1.5

Trends in Power and Energy in Integrated Circuits

Today, energy is the biggest challenge facing the computer designer for nearly every class of computer. First, power must be brought in and distributed around the chip, and modern microprocessors use hundreds of pins and multiple interconnect layers just for power and ground. Second, power is dissipated as heat and must be removed.

Power and Energy: A Systems Perspective

How should a system architect or a user think about performance, power, and energy? From the viewpoint of a system designer, there are three primary concerns.

First, what is the maximum power a processor ever requires? Meeting this demand can be important to ensuring correct operation. For example, if a processor

attempts to draw more power than a power-supply system can provide (by drawing more current than the system can supply), the result is typically a voltage drop, which can cause devices to malfunction. Modern processors can vary widely in power consumption with high peak currents; hence they provide voltage indexing methods that allow the processor to slow down and regulate voltage within a wider margin. Obviously, doing so decreases performance.

Second, what is the sustained power consumption? This metric is widely called the *thermal design power* (TDP) because it determines the cooling requirement. TDP is neither peak power, which is often 1.5 times higher, nor is it the actual average power that will be consumed during a given computation, which is likely to be lower still. A typical power supply for a system is typically sized to exceed the TDP, and a cooling system is usually designed to match or exceed TDP. Failure to provide adequate cooling will allow the junction temperature in the processor to exceed its maximum value, resulting in device failure and possibly permanent damage. Modern processors provide two features to assist in managing heat, since the highest power (and hence heat and temperature rise) can exceed the long-term average specified by the TDP. First, as the thermal temperature approaches the junction temperature limit, circuitry lowers the clock rate, thereby reducing power. Should this technique not be successful, a second thermal overload trap is activated to power down the chip.

The third factor that designers and users need to consider is energy and energy efficiency. Recall that power is simply energy per unit time: 1 watt = 1 joule per second. Which metric is the right one for comparing processors: energy or power? In general, energy is always a better metric because it is tied to a specific task and the time required for that task. In particular, the energy to complete a workload is equal to the average power times the execution time for the workload.

Thus, if we want to know which of two processors is more efficient for a given task, we need to compare energy consumption (not power) for executing the task. For example, processor A may have a 20% higher average power consumption than processor B, but if A executes the task in only 70% of the time needed by B, its energy consumption will be $1.2 \times 0.7 = 0.84$, which is clearly better.

One might argue that in a large server or cloud, it is sufficient to consider the average power, since the workload is often assumed to be infinite, but this is misleading. If our cloud were populated with processor Bs rather than As, then the cloud would do less work for the same amount of energy expended. Using energy to compare the alternatives avoids this pitfall. Whenever we have a fixed workload, whether for a warehouse-size cloud or a smartphone, comparing energy will be the right way to compare computer alternatives, because the electricity bill for the cloud and the battery lifetime for the smartphone are both determined by the energy consumed.

When is power consumption a useful measure? The primary legitimate use is as a constraint: for example, an air-cooled chip might be limited to 100 W. It can be used as a metric if the workload is fixed, but then it's just a variation of the true metric of energy per task.

Energy and Power Within a Microprocessor

For CMOS chips, the traditional primary energy consumption has been in switching transistors, also called *dynamic energy*. The energy required per transistor is proportional to the product of the capacitive load driven by the transistor and the square of the voltage:

$$\text{Energy}_{\text{dynamic}} \propto \text{Capacitive load} \times \text{Voltage}^2$$

This equation is the energy of pulse of the logic transition of $0 \rightarrow 1 \rightarrow 0$ or $1 \rightarrow 0 \rightarrow 1$. The energy of a single transition ($0 \rightarrow 1$ or $1 \rightarrow 0$) is then:

$$\text{Energy}_{\text{dynamic}} \propto 1/2 \times \text{Capacitive load} \times \text{Voltage}^2$$

The power required per transistor is just the product of the energy of a transition multiplied by the frequency of transitions:

$$\text{Power}_{\text{dynamic}} \propto 1/2 \times \text{Capacitive load} \times \text{Voltage}^2 \times \text{Frequency switched}$$

For a fixed task, slowing clock rate reduces power, but not energy.

Clearly, dynamic power and energy are greatly reduced by lowering the voltage, so voltages have dropped from 5 V to just under 1 V in 20 years. The capacitive load is a function of the number of transistors connected to an output and the technology, which determines the capacitance of the wires and the transistors.

Example Some microprocessors today are designed to have adjustable voltage, so a 15% reduction in voltage may result in a 15% reduction in frequency. What would be the impact on dynamic energy and on dynamic power?

Answer Because the capacitance is unchanged, the answer for energy is the ratio of the voltages

$$\frac{\text{Energy}_{\text{new}}}{\text{Energy}_{\text{old}}} = \frac{(\text{Voltage} \times 0.85)^2}{\text{Voltage}^2} = 0.85^2 = 0.72$$

which reduces energy to about 72% of the original. For power, we add the ratio of the frequencies

$$\frac{\text{Power}_{\text{new}}}{\text{Power}_{\text{old}}} = 0.72 \times \frac{(\text{Frequency switched} \times 0.85)}{\text{Frequency switched}} = 0.61$$

shrinking power to about 61% of the original.

As we move from one process to the next, the increase in the number of transistors switching and the frequency with which they change dominate the decrease in load capacitance and voltage, leading to an overall growth in power consumption and energy. The first microprocessors consumed less than a watt, and the first

32-bit microprocessors (such as the Intel 80386) used about 2 W, whereas a 4.0 GHz Intel Core i7-6700K consumes 95 W. Given that this heat must be dissipated from a chip that is about 1.5 cm on a side, we are near the limit of what can be cooled by air, and this is where we have been stuck for nearly a decade.

Given the preceding equation, you would expect clock frequency growth to slow down if we can't reduce voltage or increase power per chip. [Figure 1.11](#) shows that this has indeed been the case since 2003, even for the microprocessors in [Figure 1.1](#) that were the highest performers each year. Note that this period of flatter clock rates corresponds to the period of slow performance improvement range in [Figure 1.1](#).

Distributing the power, removing the heat, and preventing hot spots have become increasingly difficult challenges. Energy is now the major constraint to using transistors; in the past, it was the raw silicon area. Therefore modern

Figure 1.11 Growth in clock rate of microprocessors in [Figure 1.1](#). Between 1978 and 1986, the clock rate improved less than 15% per year while performance improved by 22% per year. During the “renaissance period” of 52% performance improvement per year between 1986 and 2003, clock rates shot up almost 40% per year. Since then, the clock rate has been nearly flat, growing at less than 2% per year, while single processor performance improved recently at just 3.5% per year.

microprocessors offer many techniques to try to improve energy efficiency despite flat clock rates and constant supply voltages:

1. *Do nothing well.* Most microprocessors today turn off the clock of inactive modules to save energy and dynamic power. For example, if no floating-point instructions are executing, the clock of the floating-point unit is disabled. If some cores are idle, their clocks are stopped.
2. *Dynamic voltage-frequency scaling (DVFS).* The second technique comes directly from the preceding formulas. PMDs, laptops, and even servers have periods of low activity where there is no need to operate at the highest clock frequency and voltages. Modern microprocessors typically offer a few clock frequencies and voltages in which to operate that use lower power and energy. [Figure 1.12](#) plots the potential power savings via DVFS for a server as the workload shrinks for three different clock rates: 2.4, 1.8, and 1 GHz. The overall server power savings is about 10%–15% for each of the two steps.
3. *Design for the typical case.* Given that PMDs and laptops are often idle, memory and storage offer low power modes to save energy. For example, DRAMs have a series of increasingly lower power modes to extend battery life in PMDs and laptops, and there have been proposals for disks that have a mode that spins more slowly when unused to save power. However, you cannot access DRAMs or disks in these modes, so you must return to fully active mode to read or write, no matter how low the access rate. As mentioned, microprocessors for PCs have been designed instead for heavy use at high operating temperatures, relying on on-chip temperature sensors to detect when activity should be reduced automatically to avoid overheating. This “emergency slowdown” allows manufacturers to design for a more typical case and then rely on this safety mechanism if someone really does run programs that consume much more power than is typical.

Figure 1.12 Energy savings for a server using an AMD Opteron microprocessor, 8 GB of DRAM, and one ATA disk. At 1.8 GHz, the server can handle at most up to two-thirds of the workload without causing service-level violations, and at 1 GHz, it can safely handle only one-third of the workload (Figure 5.11 in [Barroso and Hölzle, 2009](#)).

4. *Overclocking.* Intel started offering *Turbo mode* in 2008, where the chip decides that it is safe to run at a higher clock rate for a short time, possibly on just a few cores, until temperature starts to rise. For example, the 3.3 GHz Core i7 can run in short bursts for 3.6 GHz. Indeed, the highest-performing microprocessors each year since 2008 shown in [Figure 1.1](#) have all offered temporary overclocking of about 10% over the nominal clock rate. For single-threaded code, these microprocessors can turn off all cores but one and run it faster. Note that, although the operating system can turn off Turbo mode, there is no notification once it is enabled, so the programmers may be surprised to see their programs vary in performance because of room temperature!

Although dynamic power is traditionally thought of as the primary source of power dissipation in CMOS, static power is becoming an important issue because leakage current flows even when a transistor is off:

$$\text{Power}_{\text{static}} \propto \text{Current}_{\text{static}} \times \text{Voltage}$$

That is, static power is proportional to the number of devices.

Thus increasing the number of transistors increases power even if they are idle, and current leakage increases in processors with smaller transistor sizes. As a result, very low-power systems are even turning off the power supply (*power gating*) to inactive modules in order to control loss because of leakage. In 2011 the goal for leakage was 25% of the total power consumption, with leakage in high-performance designs sometimes far exceeding that goal. Leakage can be as high as 50% for such chips, in part because of the large SRAM caches that need power to maintain the storage values. (The S in SRAM is for static.) The only hope to stop leakage is to turn off power to the chips' subsets.

Finally, because the processor is just a portion of the whole energy cost of a system, it can make sense to use a faster, less energy-efficient processor to allow the rest of the system to go into a sleep mode. This strategy is known as *race-to-halt*.

The importance of power and energy has increased the scrutiny on the efficiency of an innovation, so the primary evaluation now is tasks per joule or performance per watt, contrary to performance per mm² of silicon as in the past. This new metric affects approaches to parallelism, as we will see in Chapters 4 and 5.

The Shift in Computer Architecture Because of Limits of Energy

As transistor improvement decelerates, computer architects must look elsewhere for improved energy efficiency. Indeed, given the energy budget, it is easy today to design a microprocessor with so many transistors that they cannot all be turned on at the same time. This phenomenon has been called *dark silicon*, in that much of a chip cannot be unused ("dark") at any moment in time because of thermal constraints. This observation has led architects to reexamine the fundamentals of processors' design in the search for a greater energy-cost performance.

[Figure 1.13](#), which lists the energy cost and area cost of the building blocks of a modern computer, reveals surprisingly large ratios. For example, a 32-bit

Energy numbers are from Mark Horowitz "Computing's Energy problem (and what we can do about it)". ISSCC 2014

Area numbers are from synthesized result using Design compiler under TSMC 45nm tech node. FP units used DesignWare Library.

Figure 1.13 Comparison of the energy and die area of arithmetic operations and energy cost of accesses to SRAM and DRAM. [Azizi][Dally]. Area is for TSMC 45 nm technology node.

floating-point addition uses 30 times as much energy as an 8-bit integer add. The area difference is even larger, by 60 times. However, the biggest difference is in memory; a 32-bit DRAM access takes 20,000 times as much energy as an 8-bit addition. A small SRAM is 125 times more energy-efficient than DRAM, which demonstrates the importance of careful uses of caches and memory buffers.

The new design principle of minimizing energy per task combined with the relative energy and area costs in Figure 1.13 have inspired a new direction for computer architecture, which we describe in Chapter 7. Domain-specific processors save energy by reducing wide floating-point operations and deploying special-purpose memories to reduce accesses to DRAM. They use those saving to provide 10–100 more (narrower) integer arithmetic units than a traditional processor. Although such processors perform only a limited set of tasks, they perform them remarkably faster and more energy efficiently than a general-purpose processor.

Like a hospital with general practitioners and medical specialists, computers in this energy-aware world will likely be combinations of general-purpose cores that can perform any task and special-purpose cores that do a few things extremely well and even more cheaply.

1.6

Trends in Cost

Although costs tend to be less important in some computer designs—specifically supercomputers—cost-sensitive designs are of growing significance. Indeed, in the past 35 years, the use of technology improvements to lower cost, as well as increase performance, has been a major theme in the computer industry.

Textbooks often ignore the cost half of cost-performance because costs change, thereby dating books, and because the issues are subtle and differ across industry segments. Nevertheless, it's essential for computer architects to have an understanding of cost and its factors in order to make intelligent decisions about whether a new feature should be included in designs where cost is an issue. (Imagine architects designing skyscrapers without any information on costs of steel beams and concrete!)

This section discusses the major factors that influence the cost of a computer and how these factors are changing over time.

The Impact of Time, Volume, and Commoditization

The cost of a manufactured computer component decreases over time even without significant improvements in the basic implementation technology. The underlying principle that drives costs down is the *learning curve*—manufacturing costs decrease over time. The learning curve itself is best measured by change in *yield*—the percentage of manufactured devices that survives the testing procedure. Whether it is a chip, a board, or a system, designs that have twice the yield will have half the cost.

Understanding how the learning curve improves yield is critical to projecting costs over a product's life. One example is that the price per megabyte of DRAM has dropped over the long term. Since DRAMs tend to be priced in close relationship to cost—except for periods when there is a shortage or an oversupply—price and cost of DRAM track closely.

Microprocessor prices also drop over time, but because they are less standardized than DRAMs, the relationship between price and cost is more complex. In a period of significant competition, price tends to track cost closely, although microprocessor vendors probably rarely sell at a loss.

Volume is a second key factor in determining cost. Increasing volumes affect cost in several ways. First, they decrease the time needed to get through the learning curve, which is partly proportional to the number of systems (or chips) manufactured. Second, volume decreases cost because it increases purchasing and manufacturing efficiency. As a rule of thumb, some designers have estimated that costs decrease about 10% for each doubling of volume. Moreover, volume decreases the amount of development costs that must be amortized by each computer, thus allowing cost and selling price to be closer and still make a profit.

Commodities are products that are sold by multiple vendors in large volumes and are essentially identical. Virtually all the products sold on the shelves of grocery stores are commodities, as are standard DRAMs, Flash memory, monitors, and keyboards. In the past 30 years, much of the personal computer industry has become a commodity business focused on building desktop and laptop computers running Microsoft Windows.

Because many vendors ship virtually identical products, the market is highly competitive. Of course, this competition decreases the gap between cost and selling

price, but it also decreases cost. Reductions occur because a commodity market has both volume and a clear product definition, which allows multiple suppliers to compete in building components for the commodity product. As a result, the overall product cost is lower because of the competition among the suppliers of the components and the volume efficiencies the suppliers can achieve. This rivalry has led to the low end of the computer business being able to achieve better price-performance than other sectors and has yielded greater growth at the low end, although with very limited profits (as is typical in any commodity business).

Cost of an Integrated Circuit

Why would a computer architecture book have a section on integrated circuit costs? In an increasingly competitive computer marketplace where standard parts—disks, Flash memory, DRAMs, and so on—are becoming a significant portion of any system's cost, integrated circuit costs are becoming a greater portion of the cost that varies between computers, especially in the high-volume, cost-sensitive portion of the market. Indeed, with PMDs' increasing reliance of whole *systems on a chip* (SOC), the cost of the integrated circuits is much of the cost of the PMD. Thus computer designers must understand the costs of chips in order to understand the costs of current computers.

Although the costs of integrated circuits have dropped exponentially, the basic process of silicon manufacture is unchanged: A *wafer* is still tested and chopped into *dies* that are packaged (see [Figures 1.14–1.16](#)). Therefore the cost of a packaged integrated circuit is

$$\text{Cost of integrated circuit} = \frac{\text{Cost of die} + \text{Cost of testing die} + \text{Cost of packaging and final test}}{\text{Final test yield}}$$

In this section, we focus on the cost of dies, summarizing the key issues in testing and packaging at the end.

Learning how to predict the number of good chips per wafer requires first learning how many dies fit on a wafer and then learning how to predict the percentage of those that will work. From there it is simple to predict cost:

$$\text{Cost of die} = \frac{\text{Cost of wafer}}{\text{Dies per wafer} \times \text{Die yield}}$$

The most interesting feature of this initial term of the chip cost equation is its sensitivity to die size, shown below.

The number of dies per wafer is approximately the area of the wafer divided by the area of the die. It can be more accurately estimated by

$$\text{Dies per wafer} = \frac{\pi \times (\text{Wafer diameter}/2)^2}{\text{Die area}} - \frac{\pi \times \text{Wafer diameter}}{\sqrt{2} \times \text{Die area}}$$

The first term is the ratio of wafer area (πr^2) to die area. The second compensates for the “square peg in a round hole” problem—rectangular dies near the periphery

Figure 1.14 Photograph of an Intel Skylake microprocessor die, which is evaluated in [Chapter 4](#).

Figure 1.15 The components of the microprocessor die in [Figure 1.14](#) are labeled with their functions.

Figure 1.16 This 200 mm diameter wafer of RISC-V dies was designed by SiFive. It has two types of RISC-V dies using an older, larger processing line. An FE310 die is 2.65 mm × 2.72 mm and an SiFive test die that is 2.89 mm × 2.72 mm. The wafer contains 1846 of the former and 1866 of the latter, totaling 3712 chips.

of round wafers. Dividing the circumference (πd) by the diagonal of a square die is approximately the number of dies along the edge.

Example Find the number of dies per 300 mm (30 cm) wafer for a die that is 1.5 cm on a side and for a die that is 1.0 cm on a side.

Answer When die area is 2.25 cm²:

$$\text{Dies per wafer} = \frac{\pi \times (30/2)^2}{2.25} - \frac{\pi \times 30}{\sqrt{2} \times 2.25} = \frac{706.9}{2.25} - \frac{94.2}{2.12} = 270$$

Because the area of the larger die is 2.25 times bigger, there are roughly 2.25 as many smaller dies per wafer:

$$\text{Dies per wafer} = \frac{\pi \times (30/2)^2}{1.00} - \frac{\pi \times 30}{\sqrt{2} \times 1.00} = \frac{706.9}{1.00} - \frac{94.2}{1.41} = 640$$

However, this formula gives only the maximum number of dies per wafer. The critical question is: What is the fraction of *good* dies on a wafer, or the *die yield*? A simple model of integrated circuit yield, which assumes that defects are randomly

distributed over the wafer and that yield is inversely proportional to the complexity of the fabrication process, leads to the following:

$$\text{Die yield} = \text{Wafer yield} \times 1 / (1 + \text{Defects per unit area} \times \text{Die area})^N$$

This Bose-Einstein formula is an empirical model developed by looking at the yield of many manufacturing lines (Sydow, 2006), and it still applies today. *Wafer yield* accounts for wafers that are completely bad and so need not be tested. For simplicity, we'll just assume the wafer yield is 100%. Defects per unit area is a measure of the random manufacturing defects that occur. In 2017 the value was typically 0.08–0.10 defects per square inch for a 28-nm node and 0.10–0.30 for the newer 16 nm node because it depends on the maturity of the process (recall the learning curve mentioned earlier). The metric versions are 0.012–0.016 defects per square centimeter for 28 nm and 0.016–0.047 for 16 nm. Finally, N is a parameter called the process-complexity factor, a measure of manufacturing difficulty. For 28 nm processes in 2017, N is 7.5–9.5. For a 16 nm process, N ranges from 10 to 14.

Example Find the die yield for dies that are 1.5 cm on a side and 1.0 cm on a side, assuming a defect density of 0.047 per cm^2 and N is 12.

Answer The total die areas are 2.25 and 1.00 cm^2 . For the larger die, the yield is

$$\text{Die yield} = 1 / (1 + 0.047 \times 2.25)^{12} \times 270 = 120$$

For the smaller die, the yield is

$$\text{Die yield} = 1 / (1 + 0.047 \times 1.00)^{12} \times 640 = 444$$

The bottom line is the number of good dies per wafer. Less than half of all the large dies are good, but nearly 70% of the small dies are good.

Although many microprocessors fall between 1.00 and 2.25 cm^2 , low-end embedded 32-bit processors are sometimes as small as 0.05 cm^2 , processors used for embedded control (for inexpensive IoT devices) are often less than 0.01 cm^2 , and high-end server and GPU chips can be as large as 8 cm^2 .

Given the tremendous price pressures on commodity products such as DRAM and SRAM, designers have included redundancy as a way to raise yield. For a number of years, DRAMs have regularly included some redundant memory cells so that a certain number of flaws can be accommodated. Designers have used similar techniques in both standard SRAMs and in large SRAM arrays used for caches within microprocessors. GPUs have 4 redundant processors out of 84 for the same reason. Obviously, the presence of redundant entries can be used to boost the yield significantly.

In 2017 processing of a 300 mm (12-inch) diameter wafer in a 28-nm technology costs between \$4000 and \$5000, and a 16-nm wafer costs about \$7000. Assuming a processed wafer cost of \$7000, the cost of the 1.00 cm^2 die would be around \$16, but the cost per die of the 2.25 cm^2 die would be about \$58, or almost four times the cost of a die that is a little over twice as large.

What should a computer designer remember about chip costs? The manufacturing process dictates the wafer cost, wafer yield, and defects per unit area, so the sole control of the designer is die area. In practice, because the number of defects per unit area is small, the number of good dies per wafer, and therefore the cost per die, grows roughly as the square of the die area. The computer designer affects die size, and thus cost, both by what functions are included on or excluded from the die and by the number of I/O pins.

Before we have a part that is ready for use in a computer, the die must be tested (to separate the good dies from the bad), packaged, and tested again after packaging. These steps all add significant costs, increasing the total by half.

The preceding analysis focused on the variable costs of producing a functional die, which is appropriate for high-volume integrated circuits. There is, however, one very important part of the fixed costs that can significantly affect the cost of an integrated circuit for low volumes (less than 1 million parts), namely, the cost of a mask set. Each step in the integrated circuit process requires a separate mask. Therefore, for modern high-density fabrication processes with up to 10 metal layers, mask costs are about \$4 million for 16 nm and \$1.5 million for 28 nm.

The good news is that semiconductor companies offer “shuttle runs” to dramatically lower the costs of tiny test chips. They lower costs by putting many small designs onto a single die to amortize the mask costs, and then later split the dies into smaller pieces for each project. Thus TSMC delivers 80–100 untested dies that are $1.57 \times 1.57 \text{ mm}$ in a 28 nm process for \$30,000 in 2017. Although these die are tiny, they offer the architect millions of transistors to play with. For example, several RISC-V processors would fit on such a die.

Although shuttle runs help with prototyping and debugging runs, they don’t address small-volume production of tens to hundreds of thousands of parts. Because mask costs are likely to continue to increase, some designers are incorporating reconfigurable logic to enhance the flexibility of a part and thus reduce the cost implications of masks.

Cost Versus Price

With the commoditization of computers, the margin between the cost to manufacture a product and the price the product sells for has been shrinking. Those margins pay for a company’s research and development (R&D), marketing, sales, manufacturing equipment maintenance, building rental, cost of financing, pretax profits, and taxes. Many engineers are surprised to find that most companies spend only 4% (in the commodity PC business) to 12% (in the high-end server business) of their income on R&D, which includes all engineering.

Cost of Manufacturing Versus Cost of Operation

For the first four editions of this book, cost meant the cost to build a computer and price meant price to purchase a computer. With the advent of WSCs, which contain tens of thousands of servers, the cost to operate the computers is significant in addition to the cost of purchase. Economists refer to these two costs as capital expenses (CAPEX) and operational expenses (OPEX).

As [Chapter 6](#) shows, the amortized purchase price of servers and networks is about half of the monthly cost to operate a WSC, assuming a short lifetime of the IT equipment of 3–4 years. About 40% of the monthly operational costs are for power use and the amortized infrastructure to distribute power and to cool the IT equipment, despite this infrastructure being amortized over 10–15 years. Thus, to lower operational costs in a WSC, computer architects need to use energy efficiently.

1.7

Dependability

Historically, integrated circuits were one of the most reliable components of a computer. Although their pins may be vulnerable, and faults may occur over communication channels, the failure rate inside the chip was very low. That conventional wisdom is changing as we head to feature sizes of 16 nm and smaller, because both transient faults and permanent faults are becoming more commonplace, so architects must design systems to cope with these challenges. This section gives a quick overview of the issues in dependability, leaving the official definition of the terms and approaches to Section D.3 in Appendix D.

Computers are designed and constructed at different layers of abstraction. We can descend recursively down through a computer seeing components enlarge themselves to full subsystems until we run into individual transistors. Although some faults are widespread, like the loss of power, many can be limited to a single component in a module. Thus utter failure of a module at one level may be considered merely a component error in a higher-level module. This distinction is helpful in trying to find ways to build dependable computers.

One difficult question is deciding when a system is operating properly. This theoretical point became concrete with the popularity of Internet services. Infrastructure providers started offering *service level agreements* (SLAs) or *service level objectives* (SLOs) to guarantee that their networking or power service would be dependable. For example, they would pay the customer a penalty if they did not meet an agreement of some hours per month. Thus an SLA could be used to decide whether the system was up or down.

Systems alternate between two states of service with respect to an SLA:

1. *Service accomplishment*, where the service is delivered as specified.
2. *Service interruption*, where the delivered service is different from the SLA.

Transitions between these two states are caused by *failures* (from state 1 to state 2) or *restorations* (2 to 1). Quantifying these transitions leads to the two main measures of dependability:

- *Module reliability* is a measure of the continuous service accomplishment (or, equivalently, of the time to failure) from a reference initial instant. Therefore the *mean time to failure* (MTTF) is a reliability measure. The reciprocal of MTTF is a rate of failures, generally reported as failures per billion hours of operation, or *FIT* (for *failures in time*). Thus an MTTF of 1,000,000 hours equals $10^9/10^6$ or 1000 FIT. Service interruption is measured as *mean time to repair* (MTTR). *Mean time between failures* (MTBF) is simply the sum of MTTF+MTTR. Although MTBF is widely used, MTTF is often the more appropriate term. If a collection of modules has exponentially distributed lifetimes—meaning that the age of a module is not important in probability of failure—the overall failure rate of the collection is the sum of the failure rates of the modules.
- *Module availability* is a measure of the service accomplishment with respect to the alternation between the two states of accomplishment and interruption. For nonredundant systems with repair, module availability is

$$\text{Module availability} = \frac{\text{MTTF}}{(\text{MTTF} + \text{MTTR})}$$

Note that reliability and availability are now quantifiable metrics, rather than synonyms for dependability. From these definitions, we can estimate reliability of a system quantitatively if we make some assumptions about the reliability of components and that failures are independent.

Example Assume a disk subsystem with the following components and MTTF:

- 10 disks, each rated at 1,000,000-hour MTTF
- 1 ATA controller, 500,000-hour MTTF
- 1 power supply, 200,000-hour MTTF
- 1 fan, 200,000-hour MTTF
- 1 ATA cable, 1,000,000-hour MTTF

Using the simplifying assumptions that the lifetimes are exponentially distributed and that failures are independent, compute the MTTF of the system as a whole.

Answer The sum of the failure rates is

$$\begin{aligned} \text{Failure rate}_{\text{system}} &= 10 \times \frac{1}{1,000,000} + \frac{1}{500,000} + \frac{1}{200,000} + \frac{1}{200,000} + \frac{1}{1,000,000} \\ &= \frac{10 + 2 + 5 + 5 + 1}{1,000,000 \text{ hours}} = \frac{23}{1,000,000} = \frac{23,000}{1,000,000,000 \text{ hours}} \end{aligned}$$

or 23,000 FIT. The MTTF for the system is just the inverse of the failure rate

$$\text{MTTF}_{\text{system}} = \frac{1}{\text{Failure rate}_{\text{system}}} = \frac{1,000,000,000 \text{ hours}}{23,000} = 43,500 \text{ hours}$$

or just under 5 years.

The primary way to cope with failure is redundancy, either in time (repeat the operation to see if it still is erroneous) or in resources (have other components to take over from the one that failed). Once the component is replaced and the system is fully repaired, the dependability of the system is assumed to be as good as new. Let's quantify the benefits of redundancy with an example.

Example Disk subsystems often have redundant power supplies to improve dependability. Using the preceding components and MTTFs, calculate the reliability of redundant power supplies. Assume that one power supply is sufficient to run the disk subsystem and that we are adding one redundant power supply.

Answer We need a formula to show what to expect when we can tolerate a failure and still provide service. To simplify the calculations, we assume that the lifetimes of the components are exponentially distributed and that there is no dependency between the component failures. MTTF for our redundant power supplies is the mean time until one power supply fails divided by the chance that the other will fail before the first one is replaced. Thus, if the chance of a second failure before repair is small, then the MTTF of the pair is large.

Since we have two power supplies and independent failures, the mean time until one supply fails is $\text{MTTF}_{\text{power supply}}/2$. A good approximation of the probability of a second failure is MTTR over the mean time until the other power supply fails. Therefore a reasonable approximation for a redundant pair of power supplies is

$$\text{MTTF}_{\text{power supply pair}} = \frac{\text{MTTF}_{\text{power supply}}/2}{\frac{\text{MTTR}_{\text{power supply}}}{\text{MTTF}_{\text{power supply}}}} = \frac{\text{MTTF}_{\text{power supply}}^2/2}{\text{MTTR}_{\text{power supply}}} = \frac{\text{MTTF}_{\text{power supply}}^2}{2 \times \text{MTTR}_{\text{power supply}}}$$

Using the preceding MTTF numbers, if we assume it takes on average 24 hours for a human operator to notice that a power supply has failed and to replace it, the reliability of the fault tolerant pair of power supplies is

$$\text{MTTF}_{\text{power supply pair}} = \frac{\text{MTTF}_{\text{power supply}}^2}{2 \times \text{MTTR}_{\text{power supply}}} = \frac{200,000^2}{2 \times 24} \cong 830,000,000$$

making the pair about 4150 times more reliable than a single power supply.

Having quantified the cost, power, and dependability of computer technology, we are ready to quantify performance.

1.8

Measuring, Reporting, and Summarizing Performance

When we say one computer is faster than another one is, what do we mean? The user of a cell phone may say a computer is faster when a program runs in less time, while an Amazon.com administrator may say a computer is faster when it completes more transactions per hour. The cell phone user wants to reduce *response time*—the time between the start and the completion of an event—also referred to as *execution time*. The operator of a WSC wants to increase *throughput*—the total amount of work done in a given time.

In comparing design alternatives, we often want to relate the performance of two different computers, say, X and Y. The phrase “X is faster than Y” is used here to mean that the response time or execution time is lower on X than on Y for the given task. In particular, “X is n times as fast as Y” will mean

$$\frac{\text{Execution time}_Y}{\text{Execution time}_X} = n$$

Since execution time is the reciprocal of performance, the following relationship holds:

$$n = \frac{\text{Execution time}_Y}{\text{Execution time}_X} = \frac{\frac{1}{\text{Performance}_Y}}{\frac{1}{\text{Performance}_X}} = \frac{\text{Performance}_X}{\text{Performance}_Y}$$

The phrase “the throughput of X is 1.3 times as fast as Y” signifies here that the number of tasks completed per unit time on computer X is 1.3 times the number completed on Y.

Unfortunately, time is not always the metric quoted in comparing the performance of computers. Our position is that the only consistent and reliable measure of performance is the execution time of real programs, and that all proposed alternatives to time as the metric or to real programs as the items measured have eventually led to misleading claims or even mistakes in computer design.

Even execution time can be defined in different ways depending on what we count. The most straightforward definition of time is called *wall-clock time*, *response time*, or *elapsed time*, which is the latency to complete a task, including storage accesses, memory accesses, input/output activities, operating system overhead—everything. With multiprogramming, the processor works on another program while waiting for I/O and may not necessarily minimize the elapsed time of one program. Thus we need a term to consider this activity. *CPU time* recognizes this distinction and means the time the processor is computing, *not* including the time waiting for I/O or running other programs. (Clearly, the response time seen by the user is the elapsed time of the program, not the CPU time.)

Computer users who routinely run the same programs would be the perfect candidates to evaluate a new computer. To evaluate a new system, these users would simply compare the execution time of their *workloads*—the mixture of programs

and operating system commands that users run on a computer. Few are in this happy situation, however. Most must rely on other methods to evaluate computers, and often other evaluators, hoping that these methods will predict performance for their usage of the new computer. One approach is benchmark programs, which are programs that many companies use to establish the relative performance of their computers.

Benchmarks

The best choice of benchmarks to measure performance is real applications, such as Google Translate mentioned in [Section 1.1](#). Attempts at running programs that are much simpler than a real application have led to performance pitfalls. Examples include

- *Kernels*, which are small, key pieces of real applications.
- *Toy programs*, which are 100-line programs from beginning programming assignments, such as Quicksort.
- *Synthetic benchmarks*, which are fake programs invented to try to match the profile and behavior of real applications, such as Dhrystone.

All three are discredited today, usually because the compiler writer and architect can conspire to make the computer appear faster on these stand-in programs than on real applications. Regrettably for your authors—who dropped the fallacy about using synthetic benchmarks to characterize performance in the fourth edition of this book since we thought all computer architects agreed it was disreputable—the synthetic program Dhrystone is still the most widely quoted benchmark for embedded processors in 2017!

Another issue is the conditions under which the benchmarks are run. One way to improve the performance of a benchmark has been with benchmark-specific compiler flags; these flags often caused transformations that would be illegal on many programs or would slow down performance on others. To restrict this process and increase the significance of the results, benchmark developers typically require the vendor to use one compiler and one set of flags for all the programs in the same language (such as C++ or C). In addition to the question of compiler flags, another question is whether source code modifications are allowed. There are three different approaches to addressing this question:

1. No source code modifications are allowed.
2. Source code modifications are allowed but are essentially impossible. For example, database benchmarks rely on standard database programs that are tens of millions of lines of code. The database companies are highly unlikely to make changes to enhance the performance for one particular computer.
3. Source modifications are allowed, as long as the altered version produces the same output.

The key issue that benchmark designers face in deciding to allow modification of the source is whether such modifications will reflect real practice and provide useful insight to users, or whether these changes simply reduce the accuracy of the benchmarks as predictors of real performance. As we will see in [Chapter 7](#), domain-specific architects often follow the third option when creating processors for well-defined tasks.

To overcome the danger of placing too many eggs in one basket, collections of benchmark applications, called *benchmark suites*, are a popular measure of performance of processors with a variety of applications. Of course, such collections are only as good as the constituent individual benchmarks. Nonetheless, a key advantage of such suites is that the weakness of any one benchmark is lessened by the presence of the other benchmarks. The goal of a benchmark suite is that it will characterize the real relative performance of two computers, particularly for programs not in the suite that customers are likely to run.

A cautionary example is the Electronic Design News Embedded Microprocessor Benchmark Consortium (or EEMBC, pronounced “embassy”) benchmarks.

It is a set of 41 kernels used to predict performance of different embedded applications: automotive/industrial, consumer, networking, office automation, and telecommunications. EEMBC reports unmodified performance and “full fury” performance, where almost anything goes. Because these benchmarks use small kernels, and because of the reporting options, EEMBC does not have the reputation of being a good predictor of relative performance of different embedded computers in the field. This lack of success is why Dhrystone, which EEMBC was trying to replace, is sadly still used.

One of the most successful attempts to create standardized benchmark application suites has been the SPEC (Standard Performance Evaluation Corporation), which had its roots in efforts in the late 1980s to deliver better benchmarks for workstations. Just as the computer industry has evolved over time, so has the need for different benchmark suites, and there are now SPEC benchmarks to cover many application classes. All the SPEC benchmark suites and their reported results are found at <http://www.spec.org>.

Although we focus our discussion on the SPEC benchmarks in many of the following sections, many benchmarks have also been developed for PCs running the Windows operating system.

Desktop Benchmarks

Desktop benchmarks divide into two broad classes: processor-intensive benchmarks and graphics-intensive benchmarks, although many graphics benchmarks include intensive processor activity. SPEC originally created a benchmark set focusing on processor performance (initially called SPEC89), which has evolved into its sixth generation: SPEC CPU2017, which follows SPEC2006, SPEC2000, SPEC95 SPEC92, and SPEC89. SPEC CPU2017 consists of a set of 10 integer benchmarks (CINT2017) and 17 floating-point benchmarks (CFP2017). [Figure 1.17](#) describes the current SPEC CPU benchmarks and their ancestry.

Figure 1.17 SPEC2017 programs and the evolution of the SPEC benchmarks over time, with integer programs above the line and floating-point programs below the line. Of the 10 SPEC2017 integer programs, 5 are written in C, 4 in C++, and 1 in Fortran. For the floating-point programs, the split is 3 in Fortran, 2 in C++, 2 in C, and 6 in mixed C, C++, and Fortran. The figure shows all 82 of the programs in the 1989, 1992, 1995, 2000, 2006, and 2017 releases. Gcc is the senior citizen of the group. Only 3 integer programs and 3 floating-point programs survived three or more generations. Although a few are carried over from generation to generation, the version of the program changes and either the input or the size of the benchmark is often expanded to increase its running time and to avoid perturbation in measurement or domination of the execution time by some factor other than CPU time. The benchmark descriptions on the left are for SPEC2017 only and do not apply to earlier versions. Programs in the same row from different generations of SPEC are generally not related; for example, fpppp is not a CFD code like bwaves.

SPEC benchmarks are real programs modified to be portable and to minimize the effect of I/O on performance. The integer benchmarks vary from part of a C compiler to a go program to a video compression. The floating-point benchmarks include molecular dynamics, ray tracing, and weather forecasting. The SPEC CPU suite is useful for processor benchmarking for both desktop systems and single-processor servers. We will see data on many of these programs throughout this book. However, these programs share little with modern programming languages and environments and the Google Translate application that [Section 1.1](#) describes. Nearly half of them are written at least partially in Fortran! They are even statically linked instead of being dynamically linked like most real programs. Alas, the SPEC2017 applications themselves may be real, but they are not inspiring. It's not clear that SPECINT2017 and SPECFP2017 capture what is exciting about computing in the 21st century.

In [Section 1.11](#), we describe pitfalls that have occurred in developing the SPEC CPUbenchmark suite, as well as the challenges in maintaining a useful and predictive benchmark suite.

SPEC CPU2017 is aimed at processor performance, but SPEC offers many other benchmarks. [Figure 1.18](#) lists the 17 SPEC benchmarks that are active in 2017.

Server Benchmarks

Just as servers have multiple functions, so are there multiple types of benchmarks. The simplest benchmark is perhaps a processor throughput-oriented benchmark. SPEC CPU2017 uses the SPEC CPU benchmarks to construct a simple throughput benchmark where the processing rate of a multiprocessor can be measured by running multiple copies (usually as many as there are processors) of each SPEC CPU benchmark and converting the CPU time into a rate. This leads to a measurement called the SPECrate, and it is a measure of request-level parallelism from [Section 1.2](#). To measure thread-level parallelism, SPEC offers what they call high-performance computing benchmarks around OpenMP and MPI as well as for accelerators such as GPUs (see [Figure 1.18](#)).

Other than SPECrate, most server applications and benchmarks have significant I/O activity arising from either storage or network traffic, including benchmarks for file server systems, for web servers, and for database and transaction-processing systems. SPEC offers both a file server benchmark (SPECsfs) and a Java server benchmark. ([Appendix D](#) discusses some file and I/O system benchmarks in detail.) SPECvirt_Sc2013 evaluates end-to-end performance of virtualized data center servers. Another SPEC benchmark measures power, which we examine in [Section 1.10](#).

Transaction-processing (TP) benchmarks measure the ability of a system to handle transactions that consist of database accesses and updates. Airline reservation systems and bank ATM systems are typical simple examples of TP; more sophisticated TP systems involve complex databases and decision-making.

Category	Name	Measures performance of
Cloud	Cloud_IaaS 2016	Cloud using NoSQL database transaction and K-Means clustering using map/reduce
CPU	CPU2017	Compute-intensive integer and floating-point workloads
Graphics and workstation performance	SPECviewperf® 12	3D graphics in systems running OpenGL and Direct X
	SPECwpc V2.0	Workstations running professional apps under the Windows OS
	SPECapcSM for 3ds Max 2015™	3D graphics running the proprietary Autodesk 3ds Max 2015 app
	SPECapcSM for Maya® 2012	3D graphics running the proprietary Autodesk 3ds Max 2012 app
	SPECapcSM for PTC Creo 3.0	3D graphics running the proprietary PTC Creo 3.0 app
	SPECapcSM for Siemens NX 9.0 and 10.0	3D graphics running the proprietary Siemens NX 9.0 or 10.0 app
High performance computing	SPECapcSM for SolidWorks 2015	3D graphics of systems running the proprietary SolidWorks 2015 CAD/CAM app
	ACCEL	Accelerator and host CPU running parallel applications using OpenCL and OpenACC
	MPI2007	MPI-parallel, floating-point, compute-intensive programs running on clusters and SMPs
High performance computing	OMP2012	Parallel apps running OpenMP
Java client/server	SPECjbb2015	Java servers
Power	SPECpower_ssjs2008	Power of volume server class computers running SPECjbb2015
Solution File Server (SFS)	SFS2014	File server throughput and response time
	SPECsfs2008	File servers utilizing the NFSv3 and CIFS protocols
Virtualization	SPECvirt_sc2013	Datacenter servers used in virtualized server consolidation

Figure 1.18 Active benchmarks from SPEC as of 2017.

In the mid-1980s, a group of concerned engineers formed the vendor-independent Transaction Processing Council (TPC) to try to create realistic and fair benchmarks for TP. The TPC benchmarks are described at <http://www.tpc.org>.

The first TPC benchmark, TPC-A, was published in 1985 and has since been replaced and enhanced by several different benchmarks. TPC-C, initially created in 1992, simulates a complex query environment. TPC-H models ad hoc decision support—the queries are unrelated and knowledge of past queries cannot be used to optimize future queries. The TPC-DI benchmark, a new data integration (DI) task also known as ETL, is an important part of data warehousing. TPC-E is an online transaction processing (OLTP) workload that simulates a brokerage firm's customer accounts.

Recognizing the controversy between traditional relational databases and “No SQL” storage solutions, TPCx-HS measures systems using the Hadoop file system running MapReduce programs, and TPC-DS measures a decision support system that uses either a relational database or a Hadoop-based system. TPC-VMS and TPCx-V measure database performance for virtualized systems, and TPC-Energy adds energy metrics to all the existing TPC benchmarks.

All the TPC benchmarks measure performance in transactions per second. In addition, they include a response time requirement so that throughput performance is measured only when the response time limit is met. To model real-world systems, higher transaction rates are also associated with larger systems, in terms of both users and the database to which the transactions are applied. Finally, the system cost for a benchmark system must be included as well to allow accurate comparisons of cost-performance. TPC modified its pricing policy so that there is a single specification for all the TPC benchmarks and to allow verification of the prices that TPC publishes.

Reporting Performance Results

The guiding principle of reporting performance measurements should be *reproducibility*—list everything another experimenter would need to duplicate the results. A SPEC benchmark report requires an extensive description of the computer and the compiler flags, as well as the publication of both the baseline and the optimized results. In addition to hardware, software, and baseline tuning parameter descriptions, a SPEC report contains the actual performance times, shown both in tabular form and as a graph. A TPC benchmark report is even more complete, because it must include results of a benchmarking audit and cost information. These reports are excellent sources for finding the real costs of computing systems, since manufacturers compete on high performance and cost-performance.

Summarizing Performance Results

In practical computer design, one must evaluate myriad design choices for their relative quantitative benefits across a suite of benchmarks believed to be relevant. Likewise, consumers trying to choose a computer will rely on performance measurements from benchmarks, which ideally are similar to the users’ applications. In both cases, it is useful to have measurements for a suite of benchmarks so that the performance of important applications is similar to that of one or more benchmarks in the suite and so that variability in performance can be understood. In the best case, the suite resembles a statistically valid sample of the application space, but such a sample requires more benchmarks than are typically found in most suites and requires a randomized sampling, which essentially no benchmark suite uses.

Once we have chosen to measure performance with a benchmark suite, we want to be able to summarize the performance results of the suite in a unique number. A simple approach to computing a summary result would be to compare the arithmetic means of the execution times of the programs in the suite. An alternative would be to add a weighting factor to each benchmark and use the weighted arithmetic mean as the single number to summarize performance. One approach is to use weights that make all programs execute an equal time on some reference computer, but this biases the results toward the performance characteristics of the reference computer.

Rather than pick weights, we could normalize execution times to a reference computer by dividing the time on the reference computer by the time on the computer being rated, yielding a ratio proportional to performance. SPEC uses this approach, calling the ratio the SPECRatio. It has a particularly useful property that matches the way we benchmark computer performance throughout this text—namely, comparing performance ratios. For example, suppose that the SPECRatio of computer A on a benchmark is 1.25 times as fast as computer B; then we know

$$1.25 = \frac{\text{SPECRatio}_A}{\text{SPECRatio}_B} = \frac{\frac{\text{Execution time}_{\text{reference}}}{\text{Execution time}_A}}{\frac{\text{Execution time}_{\text{reference}}}{\text{Execution time}_B}} = \frac{\text{Execution time}_B}{\text{Execution time}_A} = \frac{\text{Performance}_A}{\text{Performance}_B}$$

Notice that the execution times on the reference computer drop out and the choice of the reference computer is irrelevant when the comparisons are made as a ratio, which is the approach we consistently use. [Figure 1.19](#) gives an example.

Because a SPECRatio is a ratio rather than an absolute execution time, the mean must be computed using the *geometric* mean. (Because SPEC Ratios have no units, comparing SPEC Ratios arithmetically is meaningless.) The formula is

$$\text{Geometric mean} = \sqrt[n]{\prod_{i=1}^n \text{sample}_i}$$

In the case of SPEC, *sample_i* is the SPECRatio for program *i*. Using the geometric mean ensures two important properties:

1. The geometric mean of the ratios is the same as the ratio of the geometric means.
2. The ratio of the geometric means is equal to the geometric mean of the performance ratios, which implies that the choice of the reference computer is irrelevant.

Therefore the motivations to use the geometric mean are substantial, especially when we use performance ratios to make comparisons.

Example Show that the ratio of the geometric means is equal to the geometric mean of the performance ratios and that the reference computer of SPECRatio does not matter.

Answer Assume two computers A and B and a set of SPECratios for each.

$$\begin{aligned} \frac{\text{Geometric mean}_A}{\text{Geometric mean}_B} &= \frac{\sqrt[n]{\prod_{i=1}^n \text{SPECRatio } A_i}}{\sqrt[n]{\prod_{i=1}^n \text{SPECRatio } B_i}} = \sqrt[n]{\frac{\prod_{i=1}^n \text{SPECRatio } A_i}{\prod_{i=1}^n \text{SPECRatio } B_i}} \\ &= \sqrt[n]{\frac{\prod_{i=1}^n \frac{\text{Execution time}_{\text{reference}_i}}{\text{Execution time}_{A_i}}}{\prod_{i=1}^n \frac{\text{Execution time}_{\text{reference}_i}}{\text{Execution time}_{B_i}}}} = \sqrt[n]{\frac{\prod_{i=1}^n \text{Execution time}_{B_i}}{\prod_{i=1}^n \text{Execution time}_{A_i}}} = \sqrt[n]{\frac{\prod_{i=1}^n \text{Performance}_{A_i}}{\prod_{i=1}^n \text{Performance}_{B_i}}} \end{aligned}$$

That is, the ratio of the geometric means of the SPECratios of A and B is the geometric mean of the performance ratios of A to B of all the benchmarks in the suite. [Figure 1.19](#) demonstrates this validity using examples from SPEC.

Benchmarks	Sun Ultra Enterprise 2 time (seconds)	AMD A10-6800K time (seconds)	SPEC 2006Cint ratio	Intel Xeon E5-2690 time (seconds)	SPEC 2006Cint ratio	AMD/Intel times (seconds)	Intel/AMD SPEC ratios

Figure 1.19 SPEC2006Cint execution times (in seconds) for the Sun Ultra 5—the reference computer of SPEC2006—and execution times and SPECratios for the AMD A10 and Intel Xeon E5-2690. The final two columns show the ratios of execution times and SPEC ratios. This figure demonstrates the irrelevance of the reference computer in relative performance. The ratio of the execution times is identical to the ratio of the SPEC ratios, and the ratio of the geometric means ($63.7231.91/20.86 = 2.00$) is identical to the geometric mean of the ratios (2.00). [Section 1.11](#) discusses libquantum, whose performance is orders of magnitude higher than the other SPEC benchmarks.

1.9

Quantitative Principles of Computer Design

Now that we have seen how to define, measure, and summarize performance, cost, dependability, energy, and power, we can explore guidelines and principles that are useful in the design and analysis of computers. This section introduces important observations about design, as well as two equations to evaluate alternatives.

Take Advantage of Parallelism

Using parallelism is one of the most important methods for improving performance. Every chapter in this book has an example of how performance is enhanced through the exploitation of parallelism. We give three brief examples here, which are expounded on in later chapters.

Our first example is the use of parallelism at the system level. To improve the throughput performance on a typical server benchmark, such as SPECSFS or TPC-C, multiple processors and multiple storage devices can be used. The workload of handling requests can then be spread among the processors and storage devices, resulting in improved throughput. Being able to expand memory and the number of processors and storage devices is called *scalability*, and it is a valuable asset for servers. Spreading of data across many storage devices for parallel reads and writes enables data-level parallelism. SPECSFS also relies on request-level parallelism to use many processors, whereas TPC-C uses thread-level parallelism for faster processing of database queries.

At the level of an individual processor, taking advantage of parallelism among instructions is critical to achieving high performance. One of the simplest ways to do this is through pipelining. (Pipelining is explained in more detail in [Appendix C](#) and is a major focus of [Chapter 3](#).) The basic idea behind pipelining is to overlap instruction execution to reduce the total time to complete an instruction sequence. A key insight into pipelining is that not every instruction depends on its immediate predecessor, so executing the instructions completely or partially in parallel may be possible. Pipelining is the best-known example of ILP.

Parallelism can also be exploited at the level of detailed digital design. For example, set-associative caches use multiple banks of memory that are typically searched in parallel to find a desired item. Arithmetic-logical units use carry-lookahead, which uses parallelism to speed the process of computing sums from linear to logarithmic in the number of bits per operand. These are more examples of *data-level parallelism*.

Principle of Locality

Important fundamental observations have come from properties of programs. The most important program property that we regularly exploit is the *principle of locality*: programs tend to reuse data and instructions they have used recently. A widely held rule of thumb is that a program spends 90% of its execution time in only 10% of the code. An implication of locality is that we can predict with reasonable

accuracy what instructions and data a program will use in the near future based on its accesses in the recent past. The principle of locality also applies to data accesses, though not as strongly as to code accesses.

Two different types of locality have been observed. *Temporal locality* states that recently accessed items are likely to be accessed soon. *Spatial locality* says that items whose addresses are near one another tend to be referenced close together in time. We will see these principles applied in [Chapter 2](#).

Focus on the Common Case

Perhaps the most important and pervasive principle of computer design is to focus on the common case: in making a design trade-off, favor the frequent case over the infrequent case. This principle applies when determining how to spend resources, because the impact of the improvement is higher if the occurrence is commonplace.

Focusing on the common case works for energy as well as for resource allocation and performance. The instruction fetch and decode unit of a processor may be used much more frequently than a multiplier, so optimize it first. It works on dependability as well. If a database server has 50 storage devices for every processor, storage dependability will dominate system dependability.

In addition, the common case is often simpler and can be done faster than the infrequent case. For example, when adding two numbers in the processor, we can expect overflow to be a rare circumstance and can therefore improve performance by optimizing the more common case of no overflow. This emphasis may slow down the case when overflow occurs, but if that is rare, then overall performance will be improved by optimizing for the normal case.

We will see many cases of this principle throughout this text. In applying this simple principle, we have to decide what the frequent case is and how much performance can be improved by making that case faster. A fundamental law, called *Amdahl's Law*, can be used to quantify this principle.

Amdahl's Law

The performance gain that can be obtained by improving some portion of a computer can be calculated using Amdahl's Law. Amdahl's Law states that the performance improvement to be gained from using some faster mode of execution is limited by the fraction of the time the faster mode can be used.

Amdahl's Law defines the *speedup* that can be gained by using a particular feature. What is speedup? Suppose that we can make an enhancement to a computer that will improve performance when it is used. Speedup is the ratio

$$\text{Speedup} = \frac{\text{Performance for entire task using the enhancement when possible}}{\text{Performance for entire task without using the enhancement}}$$

Alternatively,

$$\text{Speedup} = \frac{\text{Execution time for entire task without using the enhancement}}{\text{Execution time for entire task using the enhancement when possible}}$$

Speedup tells us how much faster a task will run using the computer with the enhancement contrary to the original computer.

Amdahl's Law gives us a quick way to find the speedup from some enhancement, which depends on two factors:

1. *The fraction of the computation time in the original computer that can be converted to take advantage of the enhancement*—For example, if 40 seconds of the execution time of a program that takes 100 seconds in total can use an enhancement, the fraction is 40/100. This value, which we call $\text{Fraction}_{\text{enhanced}}$, is always less than or equal to 1.
2. *The improvement gained by the enhanced execution mode, that is, how much faster the task would run if the enhanced mode were used for the entire program*—This value is the time of the original mode over the time of the enhanced mode. If the enhanced mode takes, say, 4 seconds for a portion of the program, while it is 40 seconds in the original mode, the improvement is 40/4 or 10. We call this value, which is always greater than 1, $\text{Speedup}_{\text{enhanced}}$.

The execution time using the original computer with the enhanced mode will be the time spent using the unenhanced portion of the computer plus the time spent using the enhancement:

$$\text{Execution time}_{\text{new}} = \text{Execution time}_{\text{old}} \times \left((1 - \text{Fraction}_{\text{enhanced}}) + \frac{\text{Fraction}_{\text{enhanced}}}{\text{Speedup}_{\text{enhanced}}} \right)$$

The overall speedup is the ratio of the execution times:

$$\text{Speedup}_{\text{overall}} = \frac{\text{Execution time}_{\text{old}}}{\text{Execution time}_{\text{new}}} = \frac{1}{(1 - \text{Fraction}_{\text{enhanced}}) + \frac{\text{Fraction}_{\text{enhanced}}}{\text{Speedup}_{\text{enhanced}}}}$$

Example Suppose that we want to enhance the processor used for web serving. The new processor is 10 times faster on computation in the web serving application than the old processor. Assuming that the original processor is busy with computation 40% of the time and is waiting for I/O 60% of the time, what is the overall speedup gained by incorporating the enhancement?

Answer $\text{Fraction}_{\text{enhanced}} = 0.4$; $\text{Speedup}_{\text{enhanced}} = 10$; $\text{Speedup}_{\text{overall}} = \frac{1}{0.6 + \frac{0.4}{10}} = \frac{1}{0.64} \approx 1.56$

Amdahl's Law expresses the law of diminishing returns: The incremental improvement in speedup gained by an improvement of just a portion of the computation diminishes as improvements are added. An important corollary of Amdahl's Law is that if an enhancement is usable only for a fraction of a task, then we can't speed up the task by more than the reciprocal of 1 minus that fraction.

A common mistake in applying Amdahl's Law is to confuse "fraction of time converted *to use an enhancement*" and "fraction of time *after enhancement is in use*." If, instead of measuring the time that we *could use* the enhancement in a computation, we measure the time *after* the enhancement is in use, the results will be incorrect!

Amdahl's Law can serve as a guide to how much an enhancement will improve performance and how to distribute resources to improve cost-performance. The goal, clearly, is to spend resources proportional to where time is spent. Amdahl's Law is particularly useful for comparing the overall system performance of two alternatives, but it can also be applied to compare two processor design alternatives, as the following example shows.

Example A common transformation required in graphics processors is square root. Implementations of floating-point (FP) square root vary significantly in performance, especially among processors designed for graphics. Suppose FP square root (FSQRT) is responsible for 20% of the execution time of a critical graphics benchmark. One proposal is to enhance the FSQRT hardware and speed up this operation by a factor of 10. The other alternative is just to try to make all FP instructions in the graphics processor run faster by a factor of 1.6; FP instructions are responsible for half of the execution time for the application. The design team believes that they can make all FP instructions run 1.6 times faster with the same effort as required for the fast square root. Compare these two design alternatives.

Answer We can compare these two alternatives by comparing the speedups:

$$\text{Speedup}_{\text{FSQRT}} = \frac{1}{(1 - 0.2) + \frac{0.2}{10}} = \frac{1}{0.82} = 1.22$$

$$\text{Speedup}_{\text{FP}} = \frac{1}{(1 - 0.5) + \frac{0.5}{1.6}} = \frac{1}{0.8125} = 1.23$$

Improving the performance of the FP operations overall is slightly better because of the higher frequency.

Amdahl's Law is applicable beyond performance. Let's redo the reliability example from page 39 after improving the reliability of the power supply via redundancy from 200,000-hour to 830,000,000-hour MTTF, or $4150 \times$ better.

Example The calculation of the failure rates of the disk subsystem was

$$\begin{aligned} \text{Failure rate}_{\text{system}} &= 10 \times \frac{1}{1,000,000} + \frac{1}{500,000} + \frac{1}{200,000} + \frac{1}{200,000} + \frac{1}{1,000,000} \\ &= \frac{10 + 2 + 5 + 5 + 1}{1,000,000 \text{ hours}} = \frac{23}{1,000,000 \text{ hours}} \end{aligned}$$

Therefore the fraction of the failure rate that could be improved is 5 per million hours out of 23 for the whole system, or 0.22.

Answer The reliability improvement would be

$$\text{Improvement}_{\text{power supply pair}} = \frac{1}{(1 - 0.22) + \frac{0.22}{4150}} = \frac{1}{0.78} = 1.28$$

Despite an impressive $4150 \times$ improvement in reliability of one module, from the system's perspective, the change has a measurable but small benefit.

In the preceding examples, we needed the fraction consumed by the new and improved version; often it is difficult to measure these times directly. In the next section, we will see another way of doing such comparisons based on the use of an equation that decomposes the CPU execution time into three separate components. If we know how an alternative affects these three components, we can determine its overall performance. Furthermore, it is often possible to build simulators that measure these components before the hardware is actually designed.

The Processor Performance Equation

Essentially all computers are constructed using a clock running at a constant rate. These discrete time events are called *clock periods*, *clocks*, *cycles*, or *clock cycles*. Computer designers refer to the time of a clock period by its duration (e.g., 1 ns) or by its rate (e.g., 1 GHz). CPU time for a program can then be expressed two ways:

$$\text{CPU time} = \text{CPU clock cycles for a program} \times \text{Clock cycle time}$$

or

$$\text{CPU time} = \frac{\text{CPU clock cycles for a program}}{\text{Clock rate}}$$

In addition to the number of clock cycles needed to execute a program, we can also count the number of instructions executed—the *instruction path length* or *instruction count* (IC). If we know the number of clock cycles and the instruction count, we can calculate the average number of *clock cycles per instruction* (CPI). Because it is easier to work with, and because we will deal with simple processors in this chapter, we use CPI. Designers sometimes also use *instructions per clock* (IPC), which is the inverse of CPI.

CPI is computed as

$$\text{CPI} = \frac{\text{CPU clock cycles for a program}}{\text{Instruction count}}$$

This processor figure of merit provides insight into different styles of instruction sets and implementations, and we will use it extensively in the next four chapters.

By transposing the instruction count in the preceding formula, clock cycles can be defined as $IC \times CPI$. This allows us to use CPI in the execution time formula:

$$\text{CPU time} = \text{Instruction count} \times \text{Cycles per instruction} \times \text{Clock cycle time}$$

Expanding the first formula into the units of measurement shows how the pieces fit together:

$$\frac{\text{Instructions}}{\text{Program}} \times \frac{\text{Clock cycles}}{\text{Instruction}} \times \frac{\text{Seconds}}{\text{Clock cycle}} = \frac{\text{Seconds}}{\text{Program}} = \text{CPU time}$$

As this formula demonstrates, processor performance is dependent upon three characteristics: clock cycle (or rate), clock cycles per instruction, and instruction count. Furthermore, CPU time is *equally* dependent on these three characteristics; for example, a 10% improvement in any one of them leads to a 10% improvement in CPU time.

Unfortunately, it is difficult to change one parameter in complete isolation from others because the basic technologies involved in changing each characteristic are interdependent:

- *Clock cycle time*—Hardware technology and organization
- *CPI*—Organization and instruction set architecture
- *Instruction count*—Instruction set architecture and compiler technology

Luckily, many potential performance improvement techniques primarily enhance one component of processor performance with small or predictable impacts on the other two.

In designing the processor, sometimes it is useful to calculate the number of total processor clock cycles as

$$\text{CPU clock cycles} = \sum_{i=1}^n IC_i \times CPI_i$$

where IC_i represents the number of times instruction i is executed in a program and CPI_i represents the average number of clocks per instruction for instruction i . This form can be used to express CPU time as

$$\text{CPU time} = \left(\sum_{i=1}^n IC_i \times CPI_i \right) \times \text{Clock cycle time}$$

and overall CPI as

$$CPI = \frac{\sum_{i=1}^n IC_i \times CPI_i}{\text{Instruction count}} = \sum_{i=1}^n \frac{IC_i}{\text{Instruction count}} \times CPI_i$$

The latter form of the CPI calculation uses each individual CPI_i and the fraction of occurrences of that instruction in a program (i.e., $IC_i \div \text{Instruction count}$). Because it must include pipeline effects, cache misses, and any other memory system

inefficiencies, CPI_i should be measured and not just calculated from a table in the back of a reference manual.

Consider our performance example on page 52, here modified to use measurements of the frequency of the instructions and of the instruction CPI values, which, in practice, are obtained by simulation or by hardware instrumentation.

Example Suppose we made the following measurements:

Frequency of FP operations = 25%
 Average CPI of FP operations = 4.0
 Average CPI of other instructions = 1.33
 Frequency of FSQRT = 2%
 CPI of FSQRT = 20

Assume that the two design alternatives are to decrease the CPI of FSQRT to 2 or to decrease the average CPI of all FP operations to 2.5. Compare these two design alternatives using the processor performance equation.

Answer First, observe that only the CPI changes; the clock rate and instruction count remain identical. We start by finding the original CPI with neither enhancement:

$$\begin{aligned} CPI_{\text{original}} &= \sum_{i=1}^n CPI_i \times \left(\frac{IC_i}{\text{Instruction count}} \right) \\ &= (4 \times 25\%) + (1.33 \times 75\%) = 2.0 \end{aligned}$$

We can compute the CPI for the enhanced FSQRT by subtracting the cycles saved from the original CPI:

$$\begin{aligned} CPI_{\text{with new FPSQR}} &= CPI_{\text{original}} - 2\% \times (CPI_{\text{old FPSQR}} - CPI_{\text{of new FPSQR only}}) \\ &= 2.0 - 2\% \times (20 - 2) = 1.64 \end{aligned}$$

We can compute the CPI for the enhancement of all FP instructions the same way or by summing the FP and non-FP CPIs. Using the latter gives us

$$CPI_{\text{new FP}} = (75\% \times 1.33) + (25\% \times 2.5) = 1.625$$

Since the CPI of the overall FP enhancement is slightly lower, its performance will be marginally better. Specifically, the speedup for the overall FP enhancement is

$$\begin{aligned} \text{Speedup}_{\text{new FP}} &= \frac{\text{CPU time}_{\text{original}}}{\text{CPU time}_{\text{new FP}}} = \frac{IC \times \text{Clock cycle} \times CPI_{\text{original}}}{IC \times \text{Clock cycle} \times CPI_{\text{new FP}}} \\ &= \frac{CPI_{\text{original}}}{CPI_{\text{new FP}}} = \frac{2.00}{1.625} = 1.23 \end{aligned}$$

Happily, we obtained this same speedup using Amdahl's Law on page 51.

It is often possible to measure the constituent parts of the processor performance equation. Such isolated measurements are a key advantage of using the processor performance equation versus Amdahl's Law in the previous example. In particular, it may be difficult to measure things such as the fraction of execution time for which a set of instructions is responsible. In practice, this would probably be computed by summing the product of the instruction count and the CPI for each of the instructions in the set. Since the starting point is often individual instruction count and CPI measurements, the processor performance equation is incredibly useful.

To use the processor performance equation as a design tool, we need to be able to measure the various factors. For an existing processor, it is easy to obtain the execution time by measurement, and we know the default clock speed. The challenge lies in discovering the instruction count or the CPI. Most processors include counters for both instructions executed and clock cycles. By periodically monitoring these counters, it is also possible to attach execution time and instruction count to segments of the code, which can be helpful to programmers trying to understand and tune the performance of an application. Often designers or programmers will want to understand performance at a more fine-grained level than what is available from the hardware counters. For example, they may want to know why the CPI is what it is. In such cases, the simulation techniques used are like those for processors that are being designed.

Techniques that help with energy efficiency, such as dynamic voltage frequency scaling and overclocking (see [Section 1.5](#)), make this equation harder to use, because the clock speed may vary while we measure the program. A simple approach is to turn off those features to make the results reproducible. Fortunately, as performance and energy efficiency are often highly correlated—taking less time to run a program generally saves energy—it's probably safe to consider performance without worrying about the impact of DVFS or overclocking on the results.

1.10

Putting It All Together: Performance, Price, and Power

In the “Putting It All Together” sections that appear near the end of every chapter, we provide real examples that use the principles in that chapter. In this section, we look at measures of performance and power-performance in small servers using the SPECpower benchmark.

[Figure 1.20](#) shows the three multiprocessor servers we are evaluating along with their price. To keep the price comparison fair, all are Dell PowerEdge servers. The first is the PowerEdge R710, which is based on the Intel Xeon $\times 85670$ microprocessor with a clock rate of 2.93 GHz. Unlike the Intel Core i7-6700 in [Chapters 2–5](#), which has 20 cores and a 40 MB L3 cache, this Intel chip has 22 cores and a 55 MB L3 cache, although the cores themselves are identical. We selected a two-socket system—so 44 cores total—with 128 GB of ECC-protected 2400 MHz DDR4 DRAM. The next server is the PowerEdge C630, with the same processor, number of sockets, and DRAM. The main difference is a smaller rack-mountable package: “2U” high (3.5 inches) for the 730 versus “1U” (1.75 inches) for the 630.

Component	System 1		System 2		System 3	
	Cost (% Cost)		Cost (% Cost)		Cost (% Cost)	
Base server	PowerEdge R710	\$653 (7%)	PowerEdge R815	\$1437 (15%)	PowerEdge R815	\$1437 (11%)
Power supply	570 W		1100 W		1100 W	
Processor	Xeon X5670	\$3738 (40%)	Opteron 6174	\$2679 (29%)	Opteron 6174	\$5358 (42%)
Clock rate	2.93 GHz		2.20 GHz		2.20 GHz	
Total cores	12		24		48	
Sockets	2		2		4	
Cores/socket	6		12		12	
DRAM	12 GB	\$484 (5%)	16 GB	\$693 (7%)	32 GB	\$1386 (11%)
Ethernet Inter.	Dual 1-Gbit	\$199 (2%)	Dual 1-Gbit	\$199 (2%)	Dual 1-Gbit	\$199 (2%)
Disk	50 GB SSD	\$1279 (14%)	50 GB SSD	\$1279 (14%)	50 GB SSD	\$1279 (10%)
Windows OS		\$2999 (32%)		\$2999 (33%)		\$2999 (24%)
Total		\$9352 (100%)		\$9286 (100%)		\$12,658 (100%)
Max ssj_ops	910,978		926,676		1,840,450	
Max ssj_ops/\$	97		100		145	

Figure 1.20 Three Dell PowerEdge servers being measured and their prices as of July 2016. We calculated the cost of the processors by subtracting the cost of a second processor. Similarly, we calculated the overall cost of memory by seeing what the cost of extra memory was. Hence the base cost of the server is adjusted by removing the estimated cost of the default processor and memory. [Chapter 5](#) describes how these multisocket systems are connected together, and [Chapter 6](#) describes how clusters are connected together.

The third server is a cluster of 16 of the PowerEdge 630 s that is connected together with a 1 Gbit/s Ethernet switch. All are running the Oracle Java HotSpot version 1.7 Java Virtual Machine (JVM) and the Microsoft Windows Server 2012 R2 Datacenter version 6.3 operating system.

Note that because of the forces of benchmarking (see [Section 1.11](#)), these are unusually configured servers. The systems in [Figure 1.20](#) have little memory relative to the amount of computation, and just a tiny 120 GB solid-state disk. It is inexpensive to add cores if you don't need to add commensurate increases in memory and storage!

Rather than run statically linked C programs of SPEC CPU, SPECpower uses a more modern software stack written in Java. It is based on SPECjbb, and it represents the server side of business applications, with performance measured as the number of transactions per second, called *ssj_ops* for *server side Java operations per second*. It exercises not only the processor of the server, as does SPEC CPU, but also the caches, memory system, and even the multiprocessor interconnection system. In addition, it exercises the JVM, including the JIT runtime compiler and garbage collector, as well as portions of the underlying operating system.

As the last two rows of [Figure 1.20](#) show, the performance winner is the cluster of 16 R630s, which is hardly a surprise since it is by far the most expensive. The price-performance winner is the PowerEdge R630, but it barely beats the cluster at 213 versus 211 ssj-ops/\$. Amazingly, the 16 node cluster is within 1% of the same price-performances of a single node despite being 16 times as large.

While most benchmarks (and most computer architects) care only about performance of systems at peak load, computers rarely run at peak load. Indeed, Figure 6.2 in Chapter 6 shows the results of measuring the utilization of tens of thousands of servers over 6 months at Google, and less than 1% operate at an average utilization of 100%. The majority have an average utilization of between 10% and 50%. Thus the SPECpower benchmark captures power as the target workload varies from its peak in 10% intervals all the way to 0%, which is called Active Idle.

Figure 1.21 plots the ssj_ops (SSJ operations/second) per watt and the average power as the target load varies from 100% to 0%. The Intel R730 always has the lowest power and the single node R630 has the best ssj_ops per watt across each target workload level. Since watts = joules/second, this metric is proportional to SSJ operations per joule:

$$\frac{\text{ssj_operations/second}}{\text{Watt}} = \frac{\text{ssj_operations/second}}{\text{Joule/second}} = \frac{\text{ssj_operations}}{\text{Joule}}$$

Figure 1.21 Power-performance of the three servers in Figure 1.20. Ssj_ops/watt values are on the left axis, with the three columns associated with it, and watts are on the right axis, with the three lines associated with it. The horizontal axis shows the target workload, as it varies from 100% to Active Idle. The single node R630 has the best ssj_ops/watt at each workload level, but R730 consumes the lowest power at each level.

To calculate a single number to use to compare the power efficiency of systems, SPECpower uses

$$\text{Overall ssj_ops/watt} = \frac{\sum \text{ssj_ops}}{\sum \text{power}}$$

The overall ssj_ops/watt of the three servers is 10,802 for the R730, 11,157 for the R630, and 10,062 for the cluster of 16 R630s. Therefore the single node R630 has the best power-performance. Dividing by the price of the servers, the ssj_ops/watt/\$1,000 is 879 for the R730, 899 for the R630, and 789 (per node) for the 16-node cluster of R630s. Thus, after adding power, the single-node R630 is still in first place in performance/price, but now the single-node R730 is significantly more efficient than the 16-node cluster.

1.11

Fallacies and Pitfalls

The purpose of this section, which will be found in every chapter, is to explain some commonly held misbeliefs or misconceptions that you should avoid. We call such misbeliefs *fallacies*. When discussing a fallacy, we try to give a counterexample. We also discuss *pitfalls*—easily made mistakes. Often pitfalls are generalizations of principles that are true in a limited context. The purpose of these sections is to help you avoid making these errors in computers that you design.

Pitfall *All exponential laws must come to an end.*

The first to go was Dennard scaling. Dennard's 1974 observation was that power density was constant as transistors got smaller. If a transistor's linear region shrank by a factor 2, then both the current and voltage were also reduced by a factor of 2, and so the power it used fell by 4. Thus chips could be designed to operate faster and still use less power. Dennard scaling ended 30 years after it was observed, not because transistors didn't continue to get smaller but because integrated circuit dependability limited how far current and voltage could drop. The threshold voltage was driven so low that static power became a significant fraction of overall power.

The next deceleration was hard disk drives. Although there was no law for disks, in the past 30 years the maximum areal density of hard drives—which determines disk capacity—improved by 30%–100% per year. In more recent years, it has been less than 5% per year. Increasing density per drive has come primarily from adding more platters to a hard disk drive.

Next up was the venerable Moore's Law. It's been a while since the number of transistors per chip doubled every one to two years. For example, the DRAM chip introduced in 2014 contained 8B transistors, and we won't have a 16B transistor DRAM chip in mass production until 2019, but Moore's Law predicts a 64B transistor DRAM chip.

Moreover, the actual end of scaling of the planar logic transistor was even predicted to end by 2021. [Figure 1.22](#) shows the predictions of the physical gate length

Figure 1.22 Predictions of logic transistor dimensions from two editions of the ITRS report. These reports started in 2001, but 2015 will be the last edition, as the group has disbanded because of waning interest. The only companies that can produce state-of-the-art logic chips today are GlobalFoundries, Intel, Samsung, and TSMC, whereas there were 19 when the first ITRS report was released. With only four companies left, sharing of plans was too hard to sustain. From IEEE Spectrum, July 2016, “Transistors will stop shrinking in 2021, Moore’s Law Roadmap Predicts,” by Rachel Courtland.

of the logic transistor from two editions of the International Technology Roadmap for Semiconductors (ITRS). Unlike the 2013 report that projected gate lengths to reach 5 nm by 2028, the 2015 report projects the length stopping at 10 nm by 2021. Density improvements thereafter would have to come from ways other than shrinking the dimensions of transistors. It’s not as dire as the ITRS suggests, as companies like Intel and TSMC have plans to shrink to 3 nm gate lengths, but the rate of change is decreasing.

Figure 1.23 shows the changes in increases in bandwidth over time for microprocessors and DRAM—which are affected by the end of Dennard scaling and Moore’s Law—as well as for disks. The slowing of technology improvements is apparent in the dropping curves. The continued networking improvement is due to advances in fiber optics and a planned change in pulse amplitude modulation (PAM-4) allowing two-bit encoding so as to transmit information at 400 Gbit/s.

Figure 1.23 Relative bandwidth for microprocessors, networks, memory, and disks over time, based on data in Figure 1.10.

Fallacy *Multiprocessors are a silver bullet.*

The switch to multiple processors per chip around 2005 did not come from some breakthrough that dramatically simplified parallel programming or made it easy to build multicore computers. The change occurred because there was no other option due to the ILP walls and power walls. Multiple processors per chip do not guarantee lower power; it's certainly feasible to design a multicore chip that uses more power. The potential is just that it's possible to continue to improve performance by replacing a high-clock-rate, inefficient core with several lower-clock-rate, efficient cores. As technology to shrink transistors improves, it can shrink both capacitance and the supply voltage a bit so that we can get a modest increase in the

number of cores per generation. For example, for the past few years, Intel has been adding two cores per generation in their higher-end chips.

As we will see in Chapters 4 and 5, performance is now a programmer's burden. The programmers' La-Z-Boy era of relying on a hardware designer to make their programs go faster without lifting a finger is officially over. If programmers want their programs to go faster with each generation, they must make their programs more parallel.

The popular version of Moore's law—increasing performance with each generation of technology—is now up to programmers.

Pitfall *Falling prey to Amdahl's heartbreaking law.*

Virtually every practicing computer architect knows Amdahl's Law. Despite this, we almost all occasionally expend tremendous effort optimizing some feature before we measure its usage. Only when the overall speedup is disappointing do we recall that we should have measured first before we spent so much effort enhancing it!

Pitfall *A single point of failure.*

The calculations of reliability improvement using Amdahl's Law on page 53 show that dependability is no stronger than the weakest link in a chain. No matter how much more dependable we make the power supplies, as we did in our example, the single fan will limit the reliability of the disk subsystem. This Amdahl's Law observation led to a rule of thumb for fault-tolerant systems to make sure that every component was redundant so that no single component failure could bring down the whole system. Chapter 6 shows how a software layer avoids single points of failure inside WSCs.

Fallacy *Hardware enhancements that increase performance also improve energy efficiency, or are at worst energy neutral.*

Esmailzadeh et al. (2011) measured SPEC2006 on just one core of a 2.67 GHz Intel Core i7 using Turbo mode (Section 1.5). Performance increased by a factor of 1.07 when the clock rate increased to 2.94 GHz (or a factor of 1.10), but the i7 used a factor of 1.37 more joules and a factor of 1.47 more watt hours!

Fallacy *Benchmarks remain valid indefinitely.*

Several factors influence the usefulness of a benchmark as a predictor of real performance, and some change over time. A big factor influencing the usefulness of a benchmark is its ability to resist “benchmark engineering” or “benchmarking.” Once a benchmark becomes standardized and popular, there is tremendous pressure to improve performance by targeted optimizations or by aggressive interpretation of the rules for running the benchmark. Short kernels or programs that spend their time in a small amount of code are particularly vulnerable.

For example, despite the best intentions, the initial SPEC89 benchmark suite included a small kernel, called matrix300, which consisted of eight different 300×300 matrix multiplications. In this kernel, 99% of the execution time was in a single line (see SPEC, 1989). When an IBM compiler optimized this inner loop

(using a good idea called *blocking*, discussed in Chapters 2 and 4), performance improved by a factor of 9 over a prior version of the compiler! This benchmark tested compiler tuning and was not, of course, a good indication of overall performance, nor of the typical value of this particular optimization.

Figure 1.19 shows that if we ignore history, we may be forced to repeat it. SPEC Cint2006 had not been updated for a decade, giving compiler writers substantial time to hone their optimizers to this suite. Note that the SPEC ratios of all benchmarks but libquantum fall within the range of 16–52 for the AMD computer and from 22 to 78 for Intel. Libquantum runs about 250 times faster on AMD and 7300 times faster on Intel! This “miracle” is a result of optimizations by the Intel compiler that automatically parallelizes the code across 22 cores and optimizes memory by using bit packing, which packs together multiple narrow-range integers to save memory space and thus memory bandwidth. If we drop this benchmark and recalculate the geometric means, AMD SPEC Cint2006 falls from 31.9 to 26.5 and Intel from 63.7 to 41.4. The Intel computer is now about 1.5 times as fast as the AMD computer instead of 2.0 if we include libquantum, which is surely closer to their real relative performances. SPECCPU2017 dropped libquantum.

To illustrate the short lives of benchmarks, Figure 1.17 on page 43 lists the status of all 82 benchmarks from the various SPEC releases; Gcc is the lone survivor from SPEC89. Amazingly, about 70% of all programs from SPEC2000 or earlier were dropped from the next release.

Fallacy *The rated mean time to failure of disks is 1,200,000 hours or almost 140 years, so disks practically never fail.*

The current marketing practices of disk manufacturers can mislead users. How is such an MTTF calculated? Early in the process, manufacturers will put thousands of disks in a room, run them for a few months, and count the number that fail. They compute MTTF as the total number of hours that the disks worked cumulatively divided by the number that failed.

One problem is that this number far exceeds the lifetime of a disk, which is commonly assumed to be five years or 43,800 hours. For this large MTTF to make some sense, disk manufacturers argue that the model corresponds to a user who buys a disk and then keeps replacing the disk every 5 years—the planned lifetime of the disk. The claim is that if many customers (and their great-grandchildren) did this for the next century, on average they would replace a disk 27 times before a failure, or about 140 years.

A more useful measure is the percentage of disks that fail, which is called the *annual failure rate*. Assume 1000 disks with a 1,000,000-hour MTTF and that the disks are used 24 hours a day. If you replaced failed disks with a new one having the same reliability characteristics, the number that would fail in a year (8760 hours) is

$$\text{Failed disks} = \frac{\text{Number of disks} \times \text{Time period}}{\text{MTTF}} = \frac{1000 \text{ disks} \times 8760 \text{ hours/drive}}{1,000,000 \text{ hours/failure}} = 9$$

Stated alternatively, 0.9% would fail per year, or 4.4% over a 5-year lifetime.

Moreover, those high numbers are quoted assuming limited ranges of temperature and vibration; if they are exceeded, then all bets are off. A survey of disk drives in real environments (Gray and van Ingen, 2005) found that 3%–7% of drives failed per year, for an MTTF of about 125,000–300,000 hours. An even larger study found annual disk failure rates of 2%–10% (Pinheiro et al., 2007). Therefore the real-world MTTF is about 2–10 times worse than the manufacturer’s MTTF.

Fallacy *Peak performance tracks observed performance.*

The only universally true definition of peak performance is “the performance level a computer is guaranteed not to exceed.” Figure 1.24 shows the percentage of peak performance for four programs on four multiprocessors. It varies from 5% to 58%. Since the gap is so large and can vary significantly by benchmark, peak performance is not generally useful in predicting observed performance.

Figure 1.24 Percentage of peak performance for four programs on four multiprocessors scaled to 64 processors. The Earth Simulator and X1 are vector processors (see Chapter 4 and Appendix G). Not only did they deliver a higher fraction of peak performance, but they also had the highest peak performance and the lowest clock rates. Except for the Paratec program, the Power 4 and Itanium 2 systems delivered between 5% and 10% of their peak. From Oliker, L., Canning, A., Carter, J., Shalf, J., Ethier, S., 2004. Scientific computations on modern parallel vector systems. In: Proc. ACM/IEEE Conf. on Supercomputing, November 6–12, 2004, Pittsburgh, Penn., p. 10.

Pitfall *Fault detection can lower availability.*

This apparently ironic pitfall is because computer hardware has a fair amount of state that may not always be critical to proper operation. For example, it is not fatal if an error occurs in a branch predictor, because only performance may suffer.

In processors that try to exploit ILP aggressively, not all the operations are needed for correct execution of the program. [Mukherjee et al. \(2003\)](#) found that less than 30% of the operations were potentially on the critical path for the SPEC2000 benchmarks.

The same observation is true about programs. If a register is “dead” in a program—that is, the program will write the register before it is read again—then errors do not matter. If you were to crash the program upon detection of a transient fault in a dead register, it would lower availability unnecessarily.

The Sun Microsystems Division of Oracle lived this pitfall in 2000 with an L2 cache that included parity, but not error correction, in its Sun E3000 to Sun E10000 systems. The SRAMs they used to build the caches had intermittent faults, which parity detected. If the data in the cache were not modified, the processor would simply reread the data from the cache. Because the designers did not protect the cache with ECC (error-correcting code), the operating system had no choice but to report an error to dirty data and crash the program. Field engineers found no problems on inspection in more than 90% of the cases.

To reduce the frequency of such errors, Sun modified the Solaris operating system to “scrub” the cache by having a process that proactively wrote dirty data to memory. Because the processor chips did not have enough pins to add ECC, the only hardware option for dirty data was to duplicate the external cache, using the copy without the parity error to correct the error.

The pitfall is in detecting faults without providing a mechanism to correct them. These engineers are unlikely to design another computer without ECC on external caches.

1.12**Concluding Remarks**

This chapter has introduced a number of concepts and provided a quantitative framework that we will expand on throughout the book. Starting with the last edition, energy efficiency is the constant companion to performance.

In [Chapter 2](#), we start with the all-important area of memory system design. We will examine a wide range of techniques that conspire to make memory look infinitely large while still being as fast as possible. ([Appendix B](#) provides introductory material on caches for readers without much experience and background with them.) As in later chapters, we will see that hardware-software cooperation has become a key to high-performance memory systems, just as it has to high-performance pipelines. This chapter also covers virtual machines, an increasingly important technique for protection.

In [Chapter 3](#), we look at ILP, of which pipelining is the simplest and most common form. Exploiting ILP is one of the most important techniques for building

high-speed uniprocessors. [Chapter 3](#) begins with an extensive discussion of basic concepts that will prepare you for the wide range of ideas examined in both chapters. [Chapter 3](#) uses examples that span about 40 years, drawing from one of the first supercomputers (IBM 360/91) to the fastest processors on the market in 2017. It emphasizes what is called the *dynamic* or *runtime approach* to exploiting ILP. It also talks about the limits to ILP ideas and introduces multithreading, which is further developed in both [Chapters 4](#) and [5](#). [Appendix C](#) provides introductory material on pipelining for readers without much experience and background in pipelining. (We expect it to be a review for many readers, including those of our introductory text, *Computer Organization and Design: The Hardware/Software Interface*.)

[Chapter 4](#) explains three ways to exploit data-level parallelism. The classic and oldest approach is vector architecture, and we start there to lay down the principles of SIMD design. ([Appendix G](#) goes into greater depth on vector architectures.) We next explain the SIMD instruction set extensions found in most desktop microprocessors today. The third piece is an in-depth explanation of how modern graphics processing units (GPUs) work. Most GPU descriptions are written from the programmer's perspective, which usually hides how the computer really works. This section explains GPUs from an insider's perspective, including a mapping between GPU jargon and more traditional architecture terms.

[Chapter 5](#) focuses on the issue of achieving higher performance using multiple processors, or multiprocessors. Instead of using parallelism to overlap individual instructions, multiprocessing uses parallelism to allow multiple instruction streams to be executed simultaneously on different processors. Our focus is on the dominant form of multiprocessors, shared-memory multiprocessors, though we introduce other types as well and discuss the broad issues that arise in any multiprocessor. Here again we explore a variety of techniques, focusing on the important ideas first introduced in the 1980s and 1990s.

[Chapter 6](#) introduces clusters and then goes into depth on WSCs, which computer architects help design. The designers of WSCs are the professional descendants of the pioneers of supercomputers, such as Seymour Cray, in that they are designing extreme computers. WSCs contain tens of thousands of servers, and the equipment and the building that holds them cost nearly \$200 million. The concerns of price-performance and energy efficiency of the earlier chapters apply to WSCs, as does the quantitative approach to making decisions.

[Chapter 7](#) is new to this edition. It introduces domain-specific architectures as the only path forward for improved performance and energy efficiency given the end of Moore's Law and Dennard scaling. It offers guidelines on how to build effective domain-specific architectures, introduces the exciting domain of deep neural networks, describes four recent examples that take very different approaches to accelerating neural networks, and then compares their cost-performance.

This book comes with an abundance of material online (see [Preface](#) for more details), both to reduce cost and to introduce readers to a variety of advanced topics. [Figure 1.25](#) shows them all. Appendices A–C, which appear in the book, will be a review for many readers.

Appendix	Title
A	Instruction Set Principles
B	Review of Memory Hierarchies
C	Pipelining: Basic and Intermediate Concepts
D	Storage Systems
E	Embedded Systems
F	Interconnection Networks
G	Vector Processors in More Depth
H	Hardware and Software for VLIW and EPIC
I	Large-Scale Multiprocessors and Scientific Applications
J	Computer Arithmetic
K	Survey of Instruction Set Architectures
L	Advanced Concepts on Address Translation
M	Historical Perspectives and References

Figure 1.25 List of appendices.

In Appendix D, we move away from a processor-centric view and discuss issues in storage systems. We apply a similar quantitative approach, but one based on observations of system behavior and using an end-to-end approach to performance analysis. This appendix addresses the important issue of how to store and retrieve data efficiently using primarily lower-cost magnetic storage technologies. Our focus is on examining the performance of disk storage systems for typical I/O-intensive workloads, such as the OLTP benchmarks mentioned in this chapter. We extensively explore advanced topics in RAID-based systems, which use redundant disks to achieve both high performance and high availability. Finally, Appendix D introduces queuing theory, which gives a basis for trading off utilization and latency.

Appendix E applies an embedded computing perspective to the ideas of each of the chapters and early appendices.

Appendix F explores the topic of system interconnect broadly, including wide area and system area networks that allow computers to communicate.

Appendix H reviews VLIW hardware and software, which, in contrast, are less popular than when EPIC appeared on the scene just before the last edition.

Appendix I describes large-scale multiprocessors for use in high-performance computing.

Appendix J is the only appendix that remains from the first edition, and it covers computer arithmetic.

Appendix K provides a survey of instruction architectures, including the 80x86, the IBM 360, the VAX, and many RISC architectures, including ARM, MIPS, Power, RISC-V, and SPARC.

Appendix L is new and discusses advanced techniques for memory management, focusing on support for virtual machines and design of address translation

for very large address spaces. With the growth in cloud processors, these architectural enhancements are becoming more important.

We describe Appendix M next.

1.13

Historical Perspectives and References

Appendix M (available online) includes historical perspectives on the key ideas presented in each of the chapters in this text. These historical perspective sections allow us to trace the development of an idea through a series of machines or to describe significant projects. If you're interested in examining the initial development of an idea or processor or want further reading, references are provided at the end of each history. For this chapter, see Section M.2, "The Early Development of Computers," for a discussion on the early development of digital computers and performance measurement methodologies.

As you read the historical material, you'll soon come to realize that one of the important benefits of the youth of computing, compared to many other engineering fields, is that some of the pioneers are still alive—we can learn the history by simply asking them!

Case Studies and Exercises by Diana Franklin

Case Study 1: Chip Fabrication Cost

Concepts illustrated by this case study

- Fabrication Cost
- Fabrication Yield
- Defect Tolerance Through Redundancy

Many factors are involved in the price of a computer chip. Intel is spending \$7 billion to complete its Fab 42 fabrication facility for 7 nm technology. In this case study, we explore a hypothetical company in the same situation and how different design decisions involving fabrication technology, area, and redundancy affect the cost of chips.

- 1.1 [10/10] <1.6> [Figure 1.26](#) gives hypothetical relevant chip statistics that influence the cost of several current chips. In the next few exercises, you will be exploring the effect of different possible design decisions for the Intel chips.

Chip	Die Size (mm ²)	Estimated defect rate (per cm ²)	N	Manufacturing size (nm)	Transistors (billion)	Cores
BlueDragon	180	0.03	12	10	7.5	4
RedDragon	120	0.04	14	7	7.5	4
Phoenix ⁸	200	0.04	14	7	12	8

Figure 1.26 Manufacturing cost factors for several hypothetical current and future processors.

- a. [10] <1.6> What is the yield for the Phoenix chip?
 - b. [10] <1.6> Why does Phoenix have a higher defect rate than BlueDragon?
- 1.2 [20/20/20/20] <1.6> They will sell a range of chips from that factory, and they need to decide how much capacity to dedicate to each chip. Imagine that they will sell two chips. Phoenix is a completely new architecture designed with 7 nm technology in mind, whereas RedDragon is the same architecture as their 10 nm BlueDragon. Imagine that RedDragon will make a profit of \$15 per defect-free chip. Phoenix will make a profit of \$30 per defect-free chip. Each wafer has a 450 mm diameter.
- a. [20] <1.6> How much profit do you make on each wafer of Phoenix chips?
 - b. [20] <1.6> How much profit do you make on each wafer of RedDragon chips?
 - c. [20] <1.6> If your demand is 50,000 RedDragon chips per month and 25,000 Phoenix chips per month, and your facility can fabricate 70 wafers a month, how many wafers should you make of each chip?
- 1.3 [20/20] <1.6> Your colleague at AMD suggests that, since the yield is so poor, you might make chips more cheaply if you released multiple versions of the same chip, just with different numbers of cores. For example, you could sell Phoenix⁸, Phoenix⁴, Phoenix², and Phoenix¹, which contain 8, 4, 2, and 1 cores on each chip, respectively. If all eight cores are defect-free, then it is sold as Phoenix⁸. Chips with four to seven defect-free cores are sold as Phoenix⁴, and those with two or three defect-free cores are sold as Phoenix². For simplification, calculate the yield for a single core as the yield for a chip that is 1/8 the area of the original Phoenix chip. Then view that yield as an independent probability of a single core being defect free. Calculate the yield for each configuration as the probability of at the corresponding number of cores being defect free.
- a. [20] <1.6> What is the yield for a single core being defect free as well as the yield for Phoenix⁴, Phoenix² and Phoenix¹?
 - b. [5] <1.6> Using your results from part a, determine which chips you think it would be worthwhile to package and sell, and why.
 - c. [10] <1.6> If it previously cost \$20 dollars per chip to produce Phoenix⁸, what will be the cost of the new Phoenix chips, assuming that there are no additional costs associated with rescuing them from the trash?
 - d. [20] <1.6> You currently make a profit of \$30 for each defect-free Phoenix⁸, and you will sell each Phoenix⁴ chip for \$25. How much is your profit per Phoenix⁸ chip if you consider (i) the purchase price of Phoenix⁴ chips to be entirely profit and (ii) apply the profit of Phoenix⁴ chips to each Phoenix⁸ chip in proportion to how many are produced? Use the yields calculated from part Problem 1.3a, not from problem 1.1a.

Case Study 2: Power Consumption in Computer Systems

Concepts illustrated by this case study

- Amdahl's Law
- Redundancy
- MTTF
- Power Consumption

Power consumption in modern systems is dependent on a variety of factors, including the chip clock frequency, efficiency, and voltage. The following exercises explore the impact on power and energy that different design decisions and use scenarios have.

- 1.4 [10/10/10/10] <1.5> A cell phone performs very different tasks, including streaming music, streaming video, and reading email. These tasks perform very different computing tasks. Battery life and overheating are two common problems for cell phones, so reducing power and energy consumption are critical. In this problem, we consider what to do when the user is not using the phone to its full computing capacity. For these problems, we will evaluate an unrealistic scenario in which the cell phone has no specialized processing units. Instead, it has a quad-core, general-purpose processing unit. Each core uses 0.5 W at full use. For email-related tasks, the quad-core is $8\times$ as fast as necessary.
- a. [10] <1.5> How much dynamic energy and power are required compared to running at full power? First, suppose that the quad-core operates for 1/8 of the time and is idle for the rest of the time. That is, the clock is disabled for 7/8 of the time, with no leakage occurring during that time. Compare total dynamic energy as well as dynamic power while the core is running.
 - b. [10] <1.5> How much dynamic energy and power are required using frequency and voltage scaling? Assume frequency and voltage are both reduced to 1/8 the entire time.
 - c. [10] <1.6, 1.9> Now assume the voltage may not decrease below 50% of the original voltage. This voltage is referred to as the *voltage floor*, and any voltage lower than that will lose the state. Therefore, while the frequency can keep decreasing, the voltage cannot. What are the dynamic energy and power savings in this case?
 - d. [10] <1.5> How much energy is used with a dark silicon approach? This involves creating specialized ASIC hardware for each major task and power

Dynamic power

$$0.5 * 1/8$$

Dynamic ratio

$$0.5/(1/8 * 0.5)$$

$$(1/8)*(1/8)^2$$

$$(1/8)*\min(1/8, 0.5)^2$$

gating those elements when not in use. Only one general-purpose core would be provided, and the rest of the chip would be filled with specialized units. For email, the one core would operate for 25% the time and be turned completely off with power gating for the other 75% of the time. During the other 75% of the time, a specialized ASIC unit that requires 20% of the energy of a core would be running.

- 1.5 [10/10/10] <1.5> As mentioned in Exercise 1.4, cell phones run a wide variety of applications. We'll make the same assumptions for this exercise as the previous one, that it is 0.5 W per core and that a quad core runs email $3\times$ as fast.
 - a. [10] <1.5> Imagine that 80% of the code is parallelizable. By how much would the frequency and voltage on a single core need to be increased in order to execute at the same speed as the four-way parallelized code?
 - b. [10] <1.5> What is the reduction in dynamic energy from using frequency and voltage scaling in part a?
 - c. [10] <1.5> How much energy is used with a dark silicon approach? In this approach, all hardware units are power gated, allowing them to turn off entirely (causing no leakage). Specialized ASICs are provided that perform the same computation for 20% of the power as the general-purpose processor. Imagine that each core is power gated. The video game requires two ASICs and two cores. How much dynamic energy does it require compared to the baseline of parallelized on four cores?
- 1.6 [10/10/10/10/10/20] <1.5,1.9> General-purpose processes are optimized for general-purpose computing. That is, they are optimized for behavior that is generally found across a large number of applications. However, once the domain is restricted somewhat, the behavior that is found across a large number of the target applications may be different from general-purpose applications. One such application is deep learning or neural networks. Deep learning can be applied to many different applications, but the fundamental building block of inference—using the learned information to make decisions—is the same across them all. Inference operations are largely parallel, so they are currently performed on graphics processing units, which are specialized more toward this type of computation, and not to inference in particular. In a quest for more performance per watt, Google has created a custom chip using tensor processing units to accelerate inference operations in deep learning.¹ This approach can be used for speech recognition and image recognition, for example. This problem explores the trade-offs between this process, a general-purpose processor (Haswell E5-2699 v3) and a GPU (NVIDIA K80), in terms of performance and cooling. If heat is not removed from the computer efficiently, the fans will blow hot air back onto the computer, not cold air. Note: The differences are more than processor—on-chip memory and DRAM also come into play. Therefore statistics are at a system level, not a chip level.

Exercises

- 1.7 [10/15/15/10/10] <1.4, 1.5> One challenge for architects is that the design created today will require several years of implementation, verification, and testing before appearing on the market. This means that the architect must project what the technology will be like several years in advance. Sometimes, this is difficult to do.
 - a. [10] <1.4> According to the trend in device scaling historically observed by Moore's Law, the number of transistors on a chip in 2025 should be how many times the number in 2015?
 - b. [15] <1.5> The increase in performance once mirrored this trend. Had performance continued to climb at the same rate as in the 1990s, approximately what performance would chips have over the VAX-11/780 in 2025?
 - c. [15] <1.5> At the current rate of increase of the mid-2000s, what is a more updated projection of performance in 2025?
 - d. [10] <1.4> What has limited the rate of growth of the clock rate, and what are architects doing with the extra transistors now to increase performance?
 - e. [10] <1.4> The rate of growth for DRAM capacity has also slowed down. For 20 years, DRAM capacity improved by 60% each year. If 8 Gbit DRAM was first available in 2015, and 16 Gbit is not available until 2019, what is the current DRAM growth rate?
- 1.8 [10/10] <1.5> You are designing a system for a real-time application in which specific deadlines must be met. Finishing the computation faster gains nothing. You find that your system can execute the necessary code, in the worst case, twice as fast as necessary.
 - a. [10] <1.5> How much energy do you save if you execute at the current speed and turn off the system when the computation is complete?
 - b. [10] <1.5> How much energy do you save if you set the voltage and frequency to be half as much?
- 1.9 [10/10/20/20] <1.5> Server farms such as Google and Yahoo! provide enough compute capacity for the highest request rate of the day. Imagine that most of the time these servers operate at only 60% capacity. Assume further that the power does not scale linearly with the load; that is, when the servers are operating at 60% capacity, they consume 90% of maximum power. The servers could be turned off, but they would take too long to restart in response to more load. A new system has been proposed that allows for a quick restart but requires 20% of the maximum power while in this "barely alive" state.
 - a. [10] <1.5> How much power savings would be achieved by turning off 60% of the servers?
 - b. [10] <1.5> How much power savings would be achieved by placing 60% of the servers in the "barely alive" state?

- c. [20] <1.5> How much power savings would be achieved by reducing the voltage by 20% and frequency by 40%?
 - d. [20] <1.5> How much power savings would be achieved by placing 30% of the servers in the “barely alive” state and 30% off?
- 1.10 [10/10/20] <1.7> Availability is the most important consideration for designing servers, followed closely by scalability and throughput.
 - a. [10] <1.7> We have a single processor with a failure in time (FIT) of 100. What is the mean time to failure (MTTF) for this system?
 - b. [10] <1.7> If it takes one day to get the system running again, what is the availability of the system?
 - c. [20] <1.7> Imagine that the government, to cut costs, is going to build a super-computer out of inexpensive computers rather than expensive, reliable computers. What is the MTTF for a system with 1000 processors? Assume that if one fails, they all fail.
- 1.11 [20/20/20] <1.1, 1.2, 1.7> In a server farm such as that used by Amazon or eBay, a single failure does not cause the entire system to crash. Instead, it will reduce the number of requests that can be satisfied at any one time.
 - a. [20] <1.7> If a company has 10,000 computers, each with an MTTF of 35 days, and it experiences catastrophic failure only if 1/3 of the computers fail, what is the MTTF for the system?
 - b. [20] <1.1, 1.7> If it costs an extra \$1000, per computer, to double the MTTF, would this be a good business decision? Show your work.
 - c. [20] <1.2> [Figure 1.3](#) shows, on average, the cost of downtimes, assuming that the cost is equal at all times of the year. For retailers, however, the Christmas season is the most profitable (and therefore the most costly time to lose sales). If a catalog sales center has twice as much traffic in the fourth quarter as every other quarter, what is the average cost of downtime per hour during the fourth quarter and the rest of the year?
- 1.12 [20/10/10/10/15] <1.9> In this exercise, assume that we are considering enhancing a quad-core machine by adding encryption hardware to it. When computing encryption operations, it is 20 times faster than the normal mode of execution. We will define percentage of encryption as the percentage of time in the original execution that is spent performing encryption operations. The specialized hardware increases power consumption by 2%.
 - a. [20] <1.9> Draw a graph that plots the speedup as a percentage of the computation spent performing encryption. Label the y-axis “Net speedup” and label the x-axis “Percent encryption.”
 - b. [10] <1.9> With what percentage of encryption will adding encryption hardware result in a speedup of 2?
 - c. [10] <1.9> What percentage of time in the new execution will be spent on encryption operations if a speedup of 2 is achieved?

- d. [15] <1.9> Suppose you have measured the percentage of encryption to be 50%. The hardware design group estimates it can speed up the encryption hardware even more with significant additional investment. You wonder whether adding a second unit in order to support parallel encryption operations would be more useful. Imagine that in the original program, 90% of the encryption operations could be performed in parallel. What is the speedup of providing two or four encryption units, assuming that the parallelization allowed is limited to the number of encryption units?
- 1.13 [15/10] <1.9> Assume that we make an enhancement to a computer that improves some mode of execution by a factor of 10. Enhanced mode is used 50% of the time, measured as a percentage of the execution time *when the enhanced mode is in use*. Recall that Amdahl's Law depends on the fraction of the original, unenhanced execution time that could make use of enhanced mode. Thus we cannot directly use this 50% measurement to compute speedup with Amdahl's Law.
- a. [15] <1.9> What is the speedup we have obtained from fast mode?
- b. [10] <1.9> What percentage of the original execution time has been converted to fast mode?
- 1.14 [20/20/15] <1.9> When making changes to optimize part of a processor, it is often the case that speeding up one type of instruction comes at the cost of slowing down something else. For example, if we put in a complicated fast floating-point unit, that takes space, and something might have to be moved farther away from the middle to accommodate it, adding an extra cycle in delay to reach that unit. The basic Amdahl's Law equation does not take into account this trade-off.
- a. [20] <1.9> If the new fast floating-point unit speeds up floating-point operations by, on average, 2x, and floating-point operations take 20% of the original program's execution time, what is the overall speedup (ignoring the penalty to any other instructions)?
- b. [20] <1.9> Now assume that speeding up the floating-point unit slowed down data cache accesses, resulting in a 1.5x slowdown (or 2/3 speedup). Data cache accesses consume 10% of the execution time. What is the overall speedup now?
- c. [15] <1.9> After implementing the new floating-point operations, what percentage of execution time is spent on floating-point operations? What percentage is spent on data cache accesses?
- 1.15 [10/10/20/20] <1.10> Your company has just bought a new 22-core processor, and you have been tasked with optimizing your software for this processor. You will run four applications on this system, but the resource requirements are not equal. Assume the system and application characteristics listed in [Table 1.1](#).

Table 1.1 Four applications

Application	A	B	C	D
% resources needed	41	27	18	14
% parallelizable	50	80	60	90

The percentage of resources of assuming they are all run in serial. Assume that when you parallelize a portion of the program by X , the speedup for that portion is X .

- a. [10] <1.10> How much speedup would result from running application A on the entire 22-core processor, as compared to running it serially?
 - b. [10] <1.10> How much speedup would result from running application D on the entire 22-core processor, as compared to running it serially?
 - c. [20] <1.10> Given that application A requires 41% of the resources, if we statically assign it 41% of the cores, what is the overall speedup if A is run parallelized but everything else is run serially?
 - d. [20] <1.10> What is the overall speedup if all four applications are statically assigned some of the cores, relative to their percentage of resource needs, and all run parallelized?
 - e. [10] <1.10> Given acceleration through parallelization, what new percentage of the resources are the applications receiving, considering only active time on their statically-assigned cores?
- 1.16 [10/20/20/20/25] <1.10> When parallelizing an application, the ideal speedup is speeding up by the number of processors. This is limited by two things: percentage of the application that can be parallelized and the cost of communication. Amdahl's Law takes into account the former but not the latter.
- a. [10] <1.10> What is the speedup with N processors if 80% of the application is parallelizable, ignoring the cost of communication?
 - b. [20] <1.10> What is the speedup with eight processors if, for every processor added, the communication overhead is 0.5% of the original execution time.
 - c. [20] <1.10> What is the speedup with eight processors if, for every time the number of processors is doubled, the communication overhead is increased by 0.5% of the original execution time?
 - d. [20] <1.10> What is the speedup with N processors if, for every time the number of processors is doubled, the communication overhead is increased by 0.5% of the original execution time?
 - e. [25] <1.10> Write the general equation that solves this question: What is the number of processors with the highest speedup in an application in which $P\%$ of the original execution time is parallelizable, and, for every time the number of processors is doubled, the communication is increased by 0.5% of the original execution time?

Memory Hierarchy Design

Ideally one would desire an indefinitely large memory capacity such that any particular... word would be immediately available... We are... forced to recognize the possibility of constructing a hierarchy of memories each of which has greater capacity than the preceding but which is less quickly accessible.

A. W. Burks, H. H. Goldstine,
and J. von Neumann,

*Preliminary Discussion of the
Logical Design of an Electronic
Computing Instrument* (1946).

2.1

Introduction

Computer pioneers correctly predicted that programmers would want unlimited amounts of fast memory. An economical solution to that desire is a memory hierarchy, which takes advantage of locality and trade-offs in the cost-performance of memory technologies. The principle of locality, presented in the first chapter, says that most programs do not access all code or data uniformly. Locality occurs in time (temporal locality) and in space (spatial locality). This principle plus the guideline that for a given implementation technology and power budget, smaller hardware can be made faster led to hierarchies based on memories of different speeds and sizes. [Figure 2.1](#) shows several different multilevel memory hierarchies, including typical sizes and speeds of access. As Flash and next generation memory technologies continue to close the gap with disks in cost per bit, such technologies are likely to increasingly replace magnetic disks for secondary storage. As [Figure 2.1](#) shows, these technologies are already used in many personal computers and increasingly in servers, where the advantages in performance, power, and density are significant.

Because fast memory is more expensive, a memory hierarchy is organized into several levels—each smaller, faster, and more expensive per byte than the next lower level, which is farther from the processor. The goal is to provide a memory system with a cost per byte that is almost as low as the cheapest level of memory and a speed almost as fast as the fastest level. In most cases (but not all), the data contained in a lower level are a superset of the next higher level. This property, called the *inclusion property*, is always required for the lowest level of the hierarchy, which consists of main memory in the case of caches and secondary storage (disk or Flash) in the case of virtual memory.

The importance of the memory hierarchy has increased with advances in performance of processors. [Figure 2.2](#) plots single processor performance projections against the historical performance improvement in time to access main memory. The processor line shows the increase in memory requests per second on average (i.e., the inverse of the latency between memory references), while the memory line shows the increase in DRAM accesses per second (i.e., the inverse of the DRAM access latency), assuming a single DRAM and a single memory bank. The reality is more complex because the processor request rate is not uniform, and the memory system typically has multiple banks of DRAMs and channels. Although the gap in access time increased significantly for many years, the lack of significant performance improvement in single processors has led to a slowdown in the growth of the gap between processors and DRAM.

Because high-end processors have multiple cores, the bandwidth requirements are greater than for single cores. Although single-core bandwidth has grown more slowly in recent years, the gap between CPU memory demand and DRAM bandwidth continues to grow as the numbers of cores grow. A modern high-end desktop processor such as the Intel Core i7 6700 can generate two data memory references per core each clock cycle. With four cores and a 4.2 GHz clock rate, the i7 can generate a peak of 32.8 billion 64-bit data memory references per second, in addition to a peak instruction demand of about 12.8 billion 128-bit instruction

Figure 2.1 The levels in a typical memory hierarchy in a personal mobile device (PMD), such as a cell phone or tablet (A), in a laptop or desktop computer (B), and in a server (C). As we move farther away from the processor, the memory in the level below becomes slower and larger. Note that the time units change by a factor of 10^9 from pico-seconds to milliseconds in the case of magnetic disks and that the size units change by a factor of 10^{10} from thousands of bytes to tens of terabytes. If we were to add warehouse-sized computers, as opposed to just servers, the capacity scale would increase by three to six orders of magnitude. Solid-state drives (SSDs) composed of Flash are used exclusively in PMDs, and heavily in both laptops and desktops. In many desktops, the primary storage system is SSD, and expansion disks are primarily hard disk drives (HDDs). Likewise, many servers mix SSDs and HDDs.

Figure 2.2 Starting with 1980 performance as a baseline, the gap in performance, measured as the difference in the time between processor memory requests (for a single processor or core) and the latency of a DRAM access, is plotted over time. In mid-2017, AMD, Intel and Nvidia all announced chip sets using versions of HBM technology. Note that the vertical axis must be on a logarithmic scale to record the size of the processor-DRAM performance gap. The memory baseline is 64 KiB DRAM in 1980, with a 1.07 per year performance improvement in latency (see [Figure 2.4](#) on page 88). The processor line assumes a 1.25 improvement per year until 1986, a 1.52 improvement until 2000, a 1.20 improvement between 2000 and 2005, and only small improvements in processor performance (on a per-core basis) between 2005 and 2015. As you can see, until 2010 memory access times in DRAM improved slowly but consistently; since 2010 the improvement in access time has reduced, as compared with the earlier periods, although there have been continued improvements in bandwidth. See [Figure 1.1](#) in [Chapter 1](#) for more information.

references; this is a total peak demand bandwidth of 409.6 GiB/s! This incredible bandwidth is achieved by multiporting and pipelining the caches; by using three levels of caches, with two private levels per core and a shared L3; and by using a separate instruction and data cache at the first level. In contrast, the peak bandwidth for DRAM main memory, using two memory channels, is only 8% of the demand bandwidth (34.1 GiB/s). Upcoming versions are expected to have an L4 DRAM cache using embedded or stacked DRAM (see [Sections 2.2](#) and [2.3](#)).

Traditionally, designers of memory hierarchies focused on optimizing average memory access time, which is determined by the cache access time, miss rate, and miss penalty. More recently, however, power has become a major consideration. In high-end microprocessors, there may be 60 MiB or more of on-chip cache, and a large second- or third-level cache will consume significant power both as leakage when not operating (called *static power*) and as active power, as when performing a read or write (called *dynamic power*), as described in [Section 2.3](#). The problem is even more acute in processors in PMDs where the CPU is less aggressive and the power budget may be 20 to 50 times smaller. In such cases, the caches can account for 25% to 50% of the total power consumption. Thus more designs must consider both performance and power trade-offs, and we will examine both in this chapter.

Basics of Memory Hierarchies: A Quick Review

The increasing size and thus importance of this gap led to the migration of the basics of memory hierarchy into undergraduate courses in computer architecture, and even to courses in operating systems and compilers. Thus we'll start with a quick review of caches and their operation. The bulk of the chapter, however, describes more advanced innovations that attack the processor—memory performance gap.

When a word is not found in the cache, the word must be fetched from a lower level in the hierarchy (which may be another cache or the main memory) and placed in the cache before continuing. Multiple words, called a *block* (or *line*), are moved for efficiency reasons, and because they are likely to be needed soon due to spatial locality. Each cache block includes a *tag* to indicate which memory address it corresponds to.

A key design decision is where blocks (or lines) can be placed in a cache. The most popular scheme is *set associative*, where a *set* is a group of blocks in the cache. A block is first mapped onto a set, and then the block can be placed anywhere within that set. Finding a block consists of first mapping the block address to the set and then searching the set—usually in parallel—to find the block. The set is chosen by the address of the data:

$$(\text{Block address}) \bmod (\text{Number of sets in cache})$$

If there are n blocks in a set, the cache placement is called *n-way set associative*. The end points of set associativity have their own names. A *direct-mapped* cache has just one block per set (so a block is always placed in the same location), and a *fully associative* cache has just one set (so a block can be placed anywhere).

Caching data that is only read is easy because the copy in the cache and memory will be identical. Caching writes is more difficult; for example, how can the copy in the cache and memory be kept consistent? There are two main strategies. A *write-through* cache updates the item in the cache *and* writes through to update main memory. A *write-back* cache only updates the copy in the cache. When the block is about to be replaced, it is copied back to memory. Both write strategies can use a *write buffer* to allow the cache to proceed as soon as the data are placed in the buffer rather than wait for full latency to write the data into memory.

One measure of the benefits of different cache organizations is miss rate. *Miss rate* is simply the fraction of cache accesses that result in a miss—that is, the number of accesses that miss divided by the number of accesses.

To gain insights into the causes of high miss rates, which can inspire better cache designs, the three Cs model sorts all misses into three simple categories:

- *Compulsory*—The very first access to a block *cannot* be in the cache, so the block must be brought into the cache. Compulsory misses are those that occur even if you were to have an infinite-sized cache.
- *Capacity*—If the cache cannot contain all the blocks needed during execution of a program, capacity misses (in addition to compulsory misses) will occur because of blocks being discarded and later retrieved.

- *Conflict*—If the block placement strategy is not fully associative, conflict misses (in addition to compulsory and capacity misses) will occur because a block may be discarded and later retrieved if multiple blocks map to its set and accesses to the different blocks are intermingled.

Figure B.8 on page 24 shows the relative frequency of cache misses broken down by the three Cs. As mentioned in [Appendix B](#), the three C’s model is conceptual, and although its insights usually hold, it is not a definitive model for explaining the cache behavior of individual references.

As we will see in [Chapters 3 and 5](#), multithreading and multiple cores add complications for caches, both increasing the potential for capacity misses as well as adding a fourth C, for *coherency* misses due to cache flushes to keep multiple caches coherent in a multiprocessor; we will consider these issues in [Chapter 5](#).

However, miss rate can be a misleading measure for several reasons. Therefore some designers prefer measuring *misses per instruction* rather than misses per memory reference (miss rate). These two are related:

$$\frac{\text{Misses}}{\text{Instruction}} = \frac{\text{Miss rate} \times \text{Memory accesses}}{\text{Instruction count}} = \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}}$$

(This equation is often expressed in integers rather than fractions, as misses per 1000 instructions.)

The problem with both measures is that they don’t factor in the cost of a miss. A better measure is the *average memory access time*,

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

where *hit time* is the time to hit in the cache and *miss penalty* is the time to replace the block from memory (that is, the cost of a miss). Average memory access time is still an indirect measure of performance; although it is a better measure than miss rate, it is not a substitute for execution time. In [Chapter 3](#) we will see that speculative processors may execute other instructions during a miss, thereby reducing the effective miss penalty. The use of multithreading (introduced in [Chapter 3](#)) also allows a processor to tolerate misses without being forced to idle. As we will examine shortly, to take advantage of such latency tolerating techniques, we need caches that can service requests while handling an outstanding miss.

If this material is new to you, or if this quick review moves too quickly, see [Appendix B](#). It covers the same introductory material in more depth and includes examples of caches from real computers and quantitative evaluations of their effectiveness.

Section B.3 in [Appendix B](#) presents six basic cache optimizations, which we quickly review here. The appendix also gives quantitative examples of the benefits of these optimizations. We also comment briefly on the power implications of these trade-offs.

1. *Larger block size to reduce miss rate*—The simplest way to reduce the miss rate is to take advantage of spatial locality and increase the block size. Larger blocks

reduce compulsory misses, but they also increase the miss penalty. Because larger blocks lower the number of tags, they can slightly reduce static power. Larger block sizes can also increase capacity or conflict misses, especially in smaller caches. Choosing the right block size is a complex trade-off that depends on the size of cache and the miss penalty.

2. *Bigger caches to reduce miss rate*—The obvious way to reduce capacity misses is to increase cache capacity. Drawbacks include potentially longer hit time of the larger cache memory and higher cost and power. Larger caches increase both static and dynamic power.
3. *Higher associativity to reduce miss rate*—Obviously, increasing associativity reduces conflict misses. Greater associativity can come at the cost of increased hit time. As we will see shortly, associativity also increases power consumption.
4. *Multilevel caches to reduce miss penalty*—A difficult decision is whether to make the cache hit time fast, to keep pace with the high clock rate of processors, or to make the cache large to reduce the gap between the processor accesses and main memory accesses. Adding another level of cache between the original cache and memory simplifies the decision. The first-level cache can be small enough to match a fast clock cycle time, yet the second-level (or third-level) cache can be large enough to capture many accesses that would go to main memory. The focus on misses in second-level caches leads to larger blocks, bigger capacity, and higher associativity. Multilevel caches are more power-efficient than a single aggregate cache. If L1 and L2 refer, respectively, to first- and second-level caches, we can redefine the average memory access time:

$$\text{Hit time}_{L1} + \text{Miss rate}_{L1} \times (\text{Hit time}_{L2} + \text{Miss rate}_{L2} \times \text{Miss penalty}_{L2})$$

5. *Giving priority to read misses over writes to reduce miss penalty*—A write buffer is a good place to implement this optimization. Write buffers create hazards because they hold the updated value of a location needed on a read miss—that is, a read-after-write hazard through memory. One solution is to check the contents of the write buffer on a read miss. If there are no conflicts, and if the memory system is available, sending the read before the writes reduces the miss penalty. Most processors give reads priority over writes. This choice has little effect on power consumption.
6. *Avoiding address translation during indexing of the cache to reduce hit time*—Caches must cope with the translation of a virtual address from the processor to a physical address to access memory. (Virtual memory is covered in [Sections 2.4](#) and [B.4](#).) A common optimization is to use the page offset—the part that is identical in both virtual and physical addresses—to index the cache, as described in [Appendix B](#), page B.38. This virtual index/physical tag method introduces some system complications and/or limitations on the size and structure of the L1 cache, but the advantages of removing the translation lookaside buffer (TLB) access from the critical path outweigh the disadvantages.

Note that each of the preceding six optimizations has a potential disadvantage that can lead to increased, rather than decreased, average memory access time.

The rest of this chapter assumes familiarity with the preceding material and the details in [Appendix B](#). In the “Putting It All Together” section, we examine the memory hierarchy for a microprocessor designed for a high-end desktop or smaller server, the Intel Core i7 6700, as well as one designed for use in a PMD, the Arm Cortex-53, which is the basis for the processor used in several tablets and smart-phones. Within each of these classes, there is a significant diversity in approach because of the intended use of the computer.

Although the i7 6700 has more cores and bigger caches than the Intel processors designed for mobile uses, the processors have similar architectures. A processor designed for small servers, such as the i7 6700, or larger servers, such as the Intel Xeon processors, typically is running a large number of concurrent processes, often for different users. Thus memory bandwidth becomes more important, and these processors offer larger caches and more aggressive memory systems to boost that bandwidth.

In contrast, PMDs not only serve one user but generally also have smaller operating systems, usually less multitasking (running of several applications simultaneously), and simpler applications. PMDs must consider both performance and energy consumption, which determines battery life. Before we dive into more advanced cache organizations and optimizations, one needs to understand the various memory technologies and how they are evolving.

2.2

Memory Technology and Optimizations

...the one single development that put computers on their feet was the invention of a reliable form of memory, namely, the core memory. ...Its cost was reasonable, it was reliable and, because it was reliable, it could in due course be made large. (p. 209)

Maurice Wilkes.

Memoirs of a Computer Pioneer (1985)

This section describes the technologies used in a memory hierarchy, specifically in building caches and main memory. These technologies are SRAM (static random-access memory), DRAM (dynamic random-access memory), and Flash. The last of these is used as an alternative to hard disks, but because its characteristics are based on semiconductor technology, it is appropriate to include in this section.

Using SRAM addresses the need to minimize access time to caches. When a cache miss occurs, however, we need to move the data from the main memory as quickly as possible, which requires a high bandwidth memory. This high memory bandwidth can be achieved by organizing the many DRAM chips that make up the main memory into multiple memory banks and by making the memory bus wider, or by doing both.

To allow memory systems to keep up with the bandwidth demands of modern processors, memory innovations started happening inside the DRAM chips

themselves. This section describes the technology inside the memory chips and those innovative, internal organizations. Before describing the technologies and options, we need to introduce some terminology.

With the introduction of burst transfer memories, now widely used in both Flash and DRAM, memory latency is quoted using two measures—access time and cycle time. *Access time* is the time between when a read is requested and when the desired word arrives, and *cycle time* is the minimum time between unrelated requests to memory.

Virtually all computers since 1975 have used DRAMs for main memory and SRAMs for cache, with one to three levels integrated onto the processor chip with the CPU. PMDs must balance power and performance, and because they have more modest storage needs, PMDs use Flash rather than disk drives, a decision increasingly being followed by desktop computers as well.

SRAM Technology

The first letter of SRAM stands for *static*. The dynamic nature of the circuits in DRAM requires data to be written back after being read—thus the difference between the access time and the cycle time as well as the need to refresh. SRAMs don't need to refresh, so the access time is very close to the cycle time. SRAMs typically use six transistors per bit to prevent the information from being disturbed when read. SRAM needs only minimal power to retain the charge in standby mode.

In earlier times, most desktop and server systems used SRAM chips for their primary, secondary, or tertiary caches. Today, all three levels of caches are integrated onto the processor chip. In high-end server chips, there may be as many as 24 cores and up to 60 MiB of cache; such systems are often configured with 128–256 GiB of DRAM per processor chip. The access times for large, third-level, on-chip caches are typically two to eight times that of a second-level cache. Even so, the L3 access time is usually at least five times faster than a DRAM access.

On-chip, cache SRAMs are normally organized with a width that matches the block size of the cache, with the tags stored in parallel to each block. This allows an entire block to be read out or written into a single cycle. This capability is particularly useful when writing data fetched after a miss into the cache or when writing back a block that must be evicted from the cache. The access time to the cache (ignoring the hit detection and selection in a set associative cache) is proportional to the number of blocks in the cache, whereas the energy consumption depends both on the number of bits in the cache (static power) and on the number of blocks (dynamic power). Set associative caches reduce the initial access time to the memory because the size of the memory is smaller, but increase the time for hit detection and block selection, a topic we will cover in [Section 2.3](#).

DRAM Technology

As early DRAMs grew in capacity, the cost of a package with all the necessary address lines was an issue. The solution was to multiplex the address lines, thereby

Figure 2.3 Internal organization of a DRAM. Modern DRAMs are organized in banks, up to 16 for DDR4. Each bank consists of a series of rows. Sending an ACT (Activate) command opens a bank and a row and loads the row into a row buffer. When the row is in the buffer, it can be transferred by successive column addresses at whatever the width of the DRAM is (typically 4, 8, or 16 bits in DDR4) or by specifying a block transfer and the starting address. The Precharge command (PRE) closes the bank and row and readies it for a new access. Each command, as well as block transfers, are synchronized with a clock. See the next section discussing SDRAM. The row and column signals are sometimes called RAS and CAS, based on the original names of the signals.

cutting the number of address pins in half. Figure 2.3 shows the basic DRAM organization. One-half of the address is sent first during the *row access strobe* (RAS). The other half of the address, sent during the *column access strobe* (CAS), follows it. These names come from the internal chip organization, because the memory is organized as a rectangular matrix addressed by rows and columns.

An additional requirement of DRAM derives from the property signified by its first letter, *D*, for *dynamic*. To pack more bits per chip, DRAMs use only a single transistor, which effectively acts as a capacitor, to store a bit. This has two implications: first, the sensing wires that detect the charge must be precharged, which sets them “halfway” between a logical 0 and 1, allowing the small charge stored in the cell to cause a 0 or 1 to be detected by the sense amplifiers. On reading, a row is placed into a row buffer, where CAS signals can select a portion of the row to read out from the DRAM. Because reading a row destroys the information, it must be written back when the row is no longer needed. This write back happens in overlapped fashion, but in early DRAMs, it meant that the cycle time before a new row could be read was larger than the time to read a row and access a portion of that row.

In addition, to prevent loss of information as the charge in a cell leaks away (assuming it is not read or written), each bit must be “refreshed” periodically. Fortunately, all the bits in a row can be refreshed simultaneously just by reading that row and writing it back. Therefore every DRAM in the memory system must access every row within a certain time window, such as 64 ms. DRAM controllers include hardware to refresh the DRAMs periodically.

This requirement means that the memory system is occasionally unavailable because it is sending a signal telling every chip to refresh. The time for a refresh is a row activation and a precharge that also writes the row back (which takes

roughly 2/3 of the time to get a datum because no column select is needed), and this is required for each row of the DRAM. Because the memory matrix in a DRAM is conceptually square, the number of steps in a refresh is usually the square root of the DRAM capacity. DRAM designers try to keep time spent refreshing to less than 5% of the total time. So far we have presented main memory as if it operated like a Swiss train, consistently delivering the goods exactly according to schedule. In fact, with SDRAMs, a DRAM controller (usually on the processor chip) tries to optimize accesses by avoiding opening new rows and using block transfer when possible. Refresh adds another unpredictable factor.

Amdahl suggested as a rule of thumb that memory capacity should grow linearly with processor speed to keep a balanced system. Thus a 1000 MIPS processor should have 1000 MiB of memory. Processor designers rely on DRAMs to supply that demand. In the past, they expected a fourfold improvement in capacity every three years, or 55% per year. Unfortunately, the performance of DRAMs is growing at a much slower rate. The slower performance improvements arise primarily because of smaller decreases in the row access time, which is determined by issues such as power limitations and the charge capacity (and thus the size) of an individual memory cell. Before we discuss these performance trends in more detail, we need to describe the major changes that occurred in DRAMs starting in the mid-1990s.

Improving Memory Performance Inside a DRAM Chip: SDRAMs

Although very early DRAMs included a buffer allowing multiple column accesses to a single row, without requiring a new row access, they used an asynchronous interface, which meant that every column access and transfer involved overhead to synchronize with the controller. In the mid-1990s, designers added a clock signal to the DRAM interface so that the repeated transfers would not bear that overhead, thereby creating *synchronous DRAM* (SDRAM). In addition to reducing overhead, SDRAMs allowed the addition of a burst transfer mode where multiple transfers can occur without specifying a new column address. Typically, eight or more 16-bit transfers can occur without sending any new addresses by placing the DRAM in burst mode. The inclusion of such burst mode transfers has meant that there is a significant gap between the bandwidth for a stream of random accesses versus access to a block of data.

To overcome the problem of getting more bandwidth from the memory as DRAM density increased, DRAMs were made wider. Initially, they offered a four-bit transfer mode; in 2017, DDR2, DDR3, and DDR DRAMs had up to 4, 8, or 16 bit buses.

In the early 2000s, a further innovation was introduced: *double data rate* (DDR), which allows a DRAM to transfer data both on the rising and the falling edge of the memory clock, thereby doubling the peak data rate.

Finally, SDRAMs introduced *banks* to help with power management, improve access time, and allow interleaved and overlapped accesses to different banks.

Access to different banks can be overlapped with each other, and each bank has its own row buffer. Creating multiple banks inside a DRAM effectively adds another segment to the address, which now consists of bank number, row address, and column address. When an address is sent that designates a new bank, that bank must be opened, incurring an additional delay. The management of banks and row buffers is completely handled by modern memory control interfaces, so that when a subsequent access specifies the same row for an open bank, the access can happen quickly, sending only the column address.

To initiate a new access, the DRAM controller sends a bank and row number (called *Activate* in SDRAMs and formerly called RAS—row select). That command opens the row and reads the entire row into a buffer. A column address can then be sent, and the SDRAM can transfer one or more data items, depending on whether it is a single item request or a burst request. Before accessing a new row, the bank must be precharged. If the row is in the same bank, then the precharge delay is seen; however, if the row is in another bank, closing the row and precharging can overlap with accessing the new row. In synchronous DRAMs, each of these command cycles requires an integral number of clock cycles.

From 1980 to 1995, DRAMs scaled with Moore’s Law, doubling capacity every 18 months (or a factor of 4 in 3 years). From the mid-1990s to 2010, capacity increased more slowly with roughly 26 months between a doubling. From 2010 to 2016, capacity only doubled! Figure 2.4 shows the capacity and access time for various generations of DDR SDRAMs. From DDR1 to DDR3, access times improved by a factor of about 3, or about 7% per year. DDR4 improves power and bandwidth over DDR3, but has similar access latency.

As Figure 2.4 shows, DDR is a sequence of standards. DDR2 lowers power from DDR1 by dropping the voltage from 2.5 to 1.8 V and offers higher clock rates: 266, 333, and 400 MHz. DDR3 drops voltage to 1.5 V and has a maximum clock speed of 800 MHz. (As we discuss in the next section, GDDR5 is a graphics

Production year	Chip size	DRAM type	Best case access time (no precharge)			Precharge needed
			RAS time (ns)	CAS time (ns)	Total (ns)	Total (ns)
2000	256M bit	DDR1	21	21	42	63
2002	512M bit	DDR1	15	15	30	45
2004	1G bit	DDR2	15	15	30	45
2006	2G bit	DDR2	10	10	20	30
2010	4G bit	DDR3	13	13	26	39
2016	8G bit	DDR4	13	13	26	39

Figure 2.4 Capacity and access times for DDR SDRAMs by year of production. Access time is for a random memory word and assumes a new row must be opened. If the row is in a different bank, we assume the bank is precharged; if the row is not open, then a precharge is required, and the access time is longer. As the number of banks has increased, the ability to hide the precharge time has also increased. DDR4 SDRAMs were initially expected in 2014, but did not begin production until early 2016.

Standard	I/O clock rate	M transfers/s	DRAM name	MiB/s/DIMM	DIMM name
DDR1	133	266	DDR266	2128	PC2100
DDR1	150	300	DDR300	2400	PC2400
DDR1	200	400	DDR400	3200	PC3200
DDR2	266	533	DDR2-533	4264	PC4300
DDR2	333	667	DDR2-667	5336	PC5300
DDR2	400	800	DDR2-800	6400	PC6400
DDR3	533	1066	DDR3-1066	8528	PC8500
DDR3	666	1333	DDR3-1333	10,664	PC10700
DDR3	800	1600	DDR3-1600	12,800	PC12800
DDR4	1333	2666	DDR4-2666	21,300	PC21300

Figure 2.5 Clock rates, bandwidth, and names of DDR DRAMS and DIMMs in 2016. Note the numerical relationship between the columns. The third column is twice the second, and the fourth uses the number from the third column in the name of the DRAM chip. The fifth column is eight times the third column, and a rounded version of this number is used in the name of the DIMM. DDR4 saw significant first use in 2016.

RAM and is based on DDR3 DRAMs.) DDR4, which shipped in volume in early 2016, but was expected in 2014, drops the voltage to 1–1.2 V and has a maximum expected clock rate of 1600 MHz. DDR5 is unlikely to reach production quantities until 2020 or later.

With the introduction of DDR, memory designers increasingly focused on bandwidth, because improvements in access time were difficult. Wider DRAMs, burst transfers, and double data rate all contributed to rapid increases in memory bandwidth. DRAMs are commonly sold on small boards called *dual inline memory modules* (DIMMs) that contain 4–16 DRAM chips and that are normally organized to be 8 bytes wide (+ ECC) for desktop and server systems. When DDR SDRAMs are packaged as DIMMs, they are confusingly labeled by the peak *DIMM* bandwidth. Therefore the DIMM name PC3200 comes from $200 \text{ MHz} \times 2 \times 8 \text{ bytes}$, or 3200 MiB/s; it is populated with DDR SDRAM chips. Sustaining the confusion, the chips themselves are labeled with *the number of bits per second* rather than their clock rate, so a 200 MHz DDR chip is called a DDR400. Figure 2.5 shows the relationships’ I/O clock rate, transfers per second per chip, chip bandwidth, chip name, DIMM bandwidth, and DIMM name.

Reducing Power Consumption in SDRAMs

Power consumption in dynamic memory chips consists of both dynamic power used in a read or write and static or standby power; both depend on the operating voltage. In the most advanced DDR4 SDRAMs, the operating voltage has dropped to 1.2 V, significantly reducing power versus DDR2 and DDR3 SDRAMs. The addition of banks also reduced power because only the row in a single bank is read.

Figure 2.6 Power consumption for a DDR3 SDRAM operating under three conditions: low-power (shutdown) mode, typical system mode (DRAM is active 30% of the time for reads and 15% for writes), and fully active mode, where the DRAM is continuously reading or writing. Reads and writes assume bursts of eight transfers. These data are based on a Micron 1.5V 2GB DDR3-1066, although similar savings occur in DDR4 SDRAMs.

In addition to these changes, all recent SDRAMs support a power-down mode, which is entered by telling the DRAM to ignore the clock. Power-down mode disables the SDRAM, except for internal automatic refresh (without which entering power-down mode for longer than the refresh time will cause the contents of memory to be lost). [Figure 2.6](#) shows the power consumption for three situations in a 2 GB DDR3 SDRAM. The exact delay required to return from low power mode depends on the SDRAM, but a typical delay is 200 SDRAM clock cycles.

Graphics Data RAMs

GDRAMs or GSDRAMs (Graphics or Graphics Synchronous DRAMs) are a special class of DRAMs based on SDRAM designs but tailored for handling the higher bandwidth demands of graphics processing units. GDDR5 is based on DDR3 with earlier GDDRs based on DDR2. Because graphics processor units (GPUs; see [Chapter 4](#)) require more bandwidth per DRAM chip than CPUs, GDDRs have several important differences:

1. GDDRs have wider interfaces: 32-bits versus 4, 8, or 16 in current designs.
2. GDDRs have a higher maximum clock rate on the data pins. To allow a higher transfer rate without incurring signaling problems, GDRAMs normally connect directly to the GPU and are attached by soldering them to the board, unlike DRAMs, which are normally arranged in an expandable array of DIMMs.

Altogether, these characteristics let GDDRs run at two to five times the bandwidth per DRAM versus DDR3 DRAMs.

Packaging Innovation: Stacked or Embedded DRAMs

The newest innovation in 2017 in DRAMs is a packaging innovation, rather than a circuit innovation. It places multiple DRAMs in a stacked or adjacent fashion embedded within the same package as the processor. (Embedded DRAM also is used to refer to designs that place DRAM on the processor chip.) Placing the DRAM and processor in the same package lowers access latency (by shortening the delay between the DRAMs and the processor) and potentially increases bandwidth by allowing more and faster connections between the processor and DRAM; thus several producers have called it *high bandwidth memory (HBM)*.

One version of this technology places the DRAM die directly on the CPU die using solder bump technology to connect them. Assuming adequate heat management, multiple DRAM dies can be stacked in this fashion. Another approach stacks only DRAMs and abuts them with the CPU in a single package using a substrate (interposer) containing the connections. [Figure 2.7](#) shows these two different interconnection schemes. Prototypes of HBM that allow stacking of up to eight chips have been demonstrated. With special versions of SDRAMs, such a package could contain 8 GiB of memory and have data transfer rates of 1 TB/s. The 2.5D technique is currently available. Because the chips must be specifically manufactured to stack, it is quite likely that most early uses will be in high-end server chipsets.

In some applications, it may be possible to internally package enough DRAM to satisfy the needs of the application. For example, a version of an Nvidia GPU used as a node in a special-purpose cluster design is being developed using HBM, and it is likely that HBM will become a successor to GDDR5 for higher-end applications. In some cases, it may be possible to use HBM as main memory, although the cost limitations and heat removal issues currently rule out this technology for some embedded applications. In the next section, we consider the possibility of using HBM as an additional level of cache.

Figure 2.7 Two forms of die stacking. The 2.5D form is available now. 3D stacking is under development and faces heat management challenges due to the CPU.

Flash Memory

Flash memory is a type of EEPROM (electronically erasable programmable read-only memory), which is normally read-only but can be erased. The other key property of Flash memory is that it holds its contents without any power. We focus on NAND Flash, which has higher density than NOR Flash and is more suitable for large-scale nonvolatile memories; the drawback is that access is sequential and writing is slower, as we explain below.

Flash is used as the secondary storage in PMDs in the same manner that a disk functions in a laptop or server. In addition, because most PMDs have a limited amount of DRAM, Flash may also act as a level of the memory hierarchy, to a much greater extent than it might have to do in a desktop or server with a main memory that might be 10–100 times larger.

Flash uses a very different architecture and has different properties than standard DRAM. The most important differences are

1. Reads to Flash are sequential and read an entire page, which can be 512 bytes, 2 KiB, or 4 KiB. Thus NAND Flash has a long delay to access the first byte from a random address (about 25 μ S), but can supply the remainder of a page block at about 40 MiB/s. By comparison, a DDR4 SDRAM takes about 40 ns to the first byte and can transfer the rest of the row at 4.8 GiB/s. Comparing the time to transfer 2 KiB, NAND Flash takes about 75 μ S, while DDR SDRAM takes less than 500 ns, making Flash about 150 times slower. Compared to magnetic disk, however, a 2 KiB read from Flash is 300 to 500 times faster. From these numbers, we can see why Flash is not a candidate to replace DRAM for main memory, but is a candidate to replace magnetic disk.
2. Flash memory must be erased (thus the name flash for the “flash” erase process) before it is overwritten, and it is erased in blocks rather than individual bytes or words. This requirement means that when data must be written to Flash, an entire block must be assembled, either as new data or by merging the data to be written and the rest of the block’s contents. For writing, Flash is about 1500 times slower than SDRAM, and about 8–15 times as fast as magnetic disk.
3. Flash memory is nonvolatile (i.e., it keeps its contents even when power is not applied) and draws significantly less power when not reading or writing (from less than half in standby mode to zero when completely inactive).
4. Flash memory limits the number of times that any given block can be written, typically at least 100,000. By ensuring uniform distribution of written blocks throughout the memory, a system can maximize the lifetime of a Flash memory system. This technique, called *write leveling*, is handled by Flash memory controllers.
5. High-density NAND Flash is cheaper than SDRAM but more expensive than disks: roughly \$2/GiB for Flash, \$20 to \$40/GiB for SDRAM, and \$0.09/GiB for magnetic disks. In the past five years, Flash has decreased in cost at a rate that is almost twice as fast as that of magnetic disks.

Like DRAM, Flash chips include redundant blocks to allow chips with small numbers of defects to be used; the remapping of blocks is handled in the Flash chip. Flash controllers handle page transfers, provide caching of pages, and handle write leveling.

The rapid improvements in high-density Flash have been critical to the development of low-power PMDs and laptops, but they have also significantly changed both desktops, which increasingly use solid state disks, and large servers, which often combine disk and Flash-based storage.

Phase-Change Memory Technology

Phase-change memory (PCM) has been an active research area for decades. The technology typically uses a small heating element to change the state of a bulk substrate between its crystalline form and an amorphous form, which have different resistive properties. Each bit corresponds to a crosspoint in a two-dimensional network that overlays the substrate. Reading is done by sensing the resistance between an x and y point (thus the alternative name *memristor*), and writing is accomplished by applying a current to change the phase of the material. The absence of an active device (such as a transistor) should lead to lower costs and greater density than that of NAND Flash.

In 2017 Micron and Intel began delivering Xpoint memory chips that are believed to be based on PCM. The technology is expected to have much better write durability than NAND Flash and, by eliminating the need to erase a page before writing, achieve an increase in write performance versus NAND of up to a factor of ten. Read latency is also better than Flash by perhaps a factor of 2–3. Initially, it is expected to be priced slightly higher than Flash, but the advantages in write performance and write durability may make it attractive, especially for SSDs. Should this technology scale well and be able to achieve additional cost reductions, it may be the solid state technology that will depose magnetic disks, which have reigned as the primary bulk nonvolatile store for more than 50 years.

Enhancing Dependability in Memory Systems

Large caches and main memories significantly increase the possibility of errors occurring both during the fabrication process and dynamically during operation. Errors that arise from a change in circuitry and are repeatable are called *hard errors* or *permanent faults*. Hard errors can occur during fabrication, as well as from a circuit change during operation (e.g., failure of a Flash memory cell after many writes). All DRAMs, Flash memory, and most SRAMs are manufactured with spare rows so that a small number of manufacturing defects can be accommodated by programming the replacement of a defective row by a spare row. Dynamic errors, which are changes to a cell's contents, not a change in the circuitry, are called *soft errors* or *transient faults*.

Dynamic errors can be detected by parity bits and detected and fixed by the use of error correcting codes (ECCs). Because instruction caches are read-only, parity

suffices. In larger data caches and in main memory, ECC is used to allow errors to be both detected and corrected. Parity requires only one bit of overhead to detect a single error in a sequence of bits. Because a multibit error would be undetected with parity, the number of bits protected by a parity bit must be limited. One parity bit per 8 data bits is a typical ratio. ECC can detect two errors and correct a single error with a cost of 8 bits of overhead per 64 data bits.

In very large systems, the possibility of multiple errors as well as complete failure of a single memory chip becomes significant. Chipkill was introduced by IBM to solve this problem, and many very large systems, such as IBM and SUN servers and the Google Clusters, use this technology. (Intel calls their version SDDC.) Similar in nature to the RAID approach used for disks, Chipkill distributes the data and ECC information so that the complete failure of a single memory chip can be handled by supporting the reconstruction of the missing data from the remaining memory chips. Using an analysis by IBM and assuming a 10,000 processor server with 4 GiB per processor yields the following rates of unrecoverable errors in three years of operation:

- Parity only: About 90,000, or one unrecoverable (or undetected) failure every 17 minutes.
- ECC only: About 3500, or about one undetected or unrecoverable failure every 7.5 hours.
- Chipkill: About one undetected or unrecoverable failure every 2 months.

Another way to look at this is to find the maximum number of servers (each with 4 GiB) that can be protected while achieving the same error rate as demonstrated for Chipkill. For parity, even a server with only one processor will have an unrecoverable error rate higher than a 10,000-server Chipkill protected system. For ECC, a 17-server system would have about the same failure rate as a 10,000-server Chipkill system. Therefore Chipkill is a requirement for the 50,000–100,00 servers in warehouse-scale computers (see Section 6.8 of [Chapter 6](#)).

2.3

Ten Advanced Optimizations of Cache Performance

The preceding average memory access time formula gives us three metrics for cache optimizations: hit time, miss rate, and miss penalty. Given the recent trends, we add cache bandwidth and power consumption to this list. We can classify the 10 advanced cache optimizations we examine into five categories based on these metrics:

1. *Reducing the hit time*—Small and simple first-level caches and way-prediction. Both techniques also generally decrease power consumption.
2. *Increasing cache bandwidth*—Pipelined caches, multibanked caches, and non-blocking caches. These techniques have varying impacts on power consumption.

3. *Reducing the miss penalty*—Critical word first and merging write buffers. These optimizations have little impact on power.
4. *Reducing the miss rate*—Compiler optimizations. Obviously any improvement at compile time improves power consumption.
5. *Reducing the miss penalty or miss rate via parallelism*—Hardware prefetching and compiler prefetching. These optimizations generally increase power consumption, primarily because of prefetched data that are unused.

In general, the hardware complexity increases as we go through these optimizations. In addition, several of the optimizations require sophisticated compiler technology, and the final one depends on HBM. We will conclude with a summary of the implementation complexity and the performance benefits of the 10 techniques presented in [Figure 2.18](#) on page 113. Because some of these are straightforward, we cover them briefly; others require more description.

First Optimization: Small and Simple First-Level Caches to Reduce Hit Time and Power

The pressure of both a fast clock cycle and power limitations encourages limited size for first-level caches. Similarly, use of lower levels of associativity can reduce both hit time and power, although such trade-offs are more complex than those involving size.

The critical timing path in a cache hit is the three-step process of addressing the tag memory using the index portion of the address, comparing the read tag value to the address, and setting the multiplexor to choose the correct data item if the cache is set associative. Direct-mapped caches can overlap the tag check with the transmission of the data, effectively reducing hit time. Furthermore, lower levels of associativity will usually reduce power because fewer cache lines must be accessed.

Although the total amount of on-chip cache has increased dramatically with new generations of microprocessors, because of the clock rate impact arising from a larger L1 cache, the size of the L1 caches has recently increased either slightly or not at all. In many recent processors, designers have opted for more associativity rather than larger caches. An additional consideration in choosing the associativity is the possibility of eliminating address aliases; we discuss this topic shortly.

One approach to determining the impact on hit time and power consumption in advance of building a chip is to use CAD tools. CACTI is a program to estimate the access time and energy consumption of alternative cache structures on CMOS microprocessors within 10% of more detailed CAD tools. For a given minimum feature size, CACTI estimates the hit time of caches as a function of cache size, associativity, number of read/write ports, and more complex parameters. [Figure 2.8](#) shows the estimated impact on hit time as cache size and associativity are varied. Depending on cache size, for these parameters, the model suggests that the hit time for direct mapped is slightly faster than two-way set associative and that two-way set associative is 1.2 times as fast as four-way and four-way is 1.4

Figure 2.8 Relative access times generally increase as cache size and associativity are increased. These data come from the CACTI model 6.5 by [Tarjan et al. \(2005\)](#). The data assume typical embedded SRAM technology, a single bank, and 64-byte blocks. The assumptions about cache layout and the complex trade-offs between interconnect delays (that depend on the size of a cache block being accessed) and the cost of tag checks and multiplexing lead to results that are occasionally surprising, such as the lower access time for a 64 KiB with two-way set associativity versus direct mapping. Similarly, the results with eight-way set associativity generate unusual behavior as cache size is increased. Because such observations are highly dependent on technology and detailed design assumptions, tools such as CACTI serve to reduce the search space. These results are relative; nonetheless, they are likely to shift as we move to more recent and denser semiconductor technologies.

times as fast as eight-way. Of course, these estimates depend on technology as well as the size of the cache, and CACTI must be carefully aligned with the technology; [Figure 2.8](#) shows the relative tradeoffs for one technology.

Example Using the data in [Figure B.8](#) in [Appendix B](#) and [Figure 2.8](#), determine whether a 32 KiB four-way set associative L1 cache has a faster memory access time than a 32 KiB two-way set associative L1 cache. Assume the miss penalty to L2 is 15 times the access time for the faster L1 cache. Ignore misses beyond L2. Which has the faster average memory access time?

Answer Let the access time for the two-way set associative cache be 1. Then, for the two-way cache,

$$\begin{aligned} \text{Average memory access time}_{2\text{-way}} &= \text{Hit time} + \text{Miss rate} \times \text{Miss penalty} \\ &= 1 + 0.038 \times 15 = 1.38 \end{aligned}$$

For the four-way cache, the access time is 1.4 times longer. The elapsed time of the miss penalty is $15/1.4 = 10.1$. Assume 10 for simplicity:

$$\begin{aligned}\text{Average memory access time}_{4\text{-way}} &= \text{Hit time}_{2\text{-way}} \times 1.4 + \text{Miss rate} \times \text{Miss penalty} \\ &= 1.4 + 0.037 \times 10 = 1.77\end{aligned}$$

Clearly, the higher associativity looks like a bad trade-off; however, because cache access in modern processors is often pipelined, the exact impact on the clock cycle time is difficult to assess.

Energy consumption is also a consideration in choosing both the cache size and associativity, as Figure 2.9 shows. The energy cost of higher associativity ranges from more than a factor of 2 to negligible in caches of 128 or 256 KiB when going from direct mapped to two-way set associative.

As energy consumption has become critical, designers have focused on ways to reduce the energy needed for cache access. In addition to associativity, the other key factor in determining the energy used in a cache access is the number of blocks in the cache because it determines the number of “rows” that are accessed. A designer could reduce the number of rows by increasing the block size (holding total cache size constant), but this could increase the miss rate, especially in smaller L1 caches.

Figure 2.9 Energy consumption per read increases as cache size and associativity are increased. As in the previous figure, CACTI is used for the modeling with the same technology parameters. The large penalty for eight-way set associative caches is due to the cost of reading out eight tags and the corresponding data in parallel.

An alternative is to organize the cache in banks so that an access activates only a portion of the cache, namely the bank where the desired block resides. The primary use of multibanked caches is to increase the bandwidth of the cache, an optimization we consider shortly. Multibanking also reduces energy because less of the cache is accessed. The L3 caches in many multicores are logically unified, but physically distributed, and effectively act as a multibanked cache. Based on the address of a request, only one of the physical L3 caches (a bank) is actually accessed. We discuss this organization further in [Chapter 5](#).

In recent designs, there are three other factors that have led to the use of higher associativity in first-level caches despite the energy and access time costs. First, many processors take at least 2 clock cycles to access the cache and thus the impact of a longer hit time may not be critical. Second, to keep the TLB out of the critical path (a delay that would be larger than that associated with increased associativity), almost all L1 caches should be virtually indexed. This limits the size of the cache to the page size times the associativity because then only the bits within the page are used for the index. There are other solutions to the problem of indexing the cache before address translation is completed, but increasing the associativity, which also has other benefits, is the most attractive. Third, with the introduction of multithreading (see [Chapter 3](#)), conflict misses can increase, making higher associativity more attractive.

Second Optimization: Way Prediction to Reduce Hit Time

Another approach reduces conflict misses and yet maintains the hit speed of direct-mapped cache. In *way prediction*, extra bits are kept in the cache to predict the way (or block within the set) of the *next* cache access. This prediction means the multiplexor is set early to select the desired block, and in that clock cycle, only a single tag comparison is performed in parallel with reading the cache data. A miss results in checking the other blocks for matches in the next clock cycle.

Added to each block of a cache are block predictor bits. The bits select which of the blocks to try on the next cache access. If the predictor is correct, the cache access latency is the fast hit time. If not, it tries the other block, changes the way predictor, and has a latency of one extra clock cycle. Simulations suggest that set prediction accuracy is in excess of 90% for a two-way set associative cache and 80% for a four-way set associative cache, with better accuracy on I-caches than D-caches. Way prediction yields lower average memory access time for a two-way set associative cache if it is at least 10% faster, which is quite likely. Way prediction was first used in the MIPS R10000 in the mid-1990s. It is popular in processors that use two-way set associativity and was used in several ARM processors, which have four-way set associative caches. For very fast processors, it may be challenging to implement the one-cycle stall that is critical to keeping the way prediction penalty small.

An extended form of way prediction can also be used to reduce power consumption by using the way prediction bits to decide which cache block to actually

access (the way prediction bits are essentially extra address bits); this approach, which might be called way selection, saves power when the way prediction is correct but adds significant time on a way misprediction, because the access, not just the tag match and selection, must be repeated. Such an optimization is likely to make sense only in low-power processors. Inoue et al. (1999) estimated that using the way selection approach with a four-way set associative cache increases the average access time for the I-cache by 1.04 and for the D-cache by 1.13 on the SPEC95 benchmarks, but it yields an average cache power consumption relative to a normal four-way set associative cache that is 0.28 for the I-cache and 0.35 for the D-cache. One significant drawback for way selection is that it makes it difficult to pipeline the cache access; however, as energy concerns have mounted, schemes that do not require powering up the entire cache make increasing sense.

Example Assume that there are half as many D-cache accesses as I-cache accesses and that the I-cache and D-cache are responsible for 25% and 15% of the processor's power consumption in a normal four-way set associative implementation. Determine if way selection improves performance per watt based on the estimates from the preceding study.

Answer For the I-cache, the savings in power is $25 \times 0.28 = 0.07$ of the total power, while for the D-cache it is $15 \times 0.35 = 0.05$ for a total savings of 0.12. The way prediction version requires 0.88 of the power requirement of the standard four-way cache. The increase in cache access time is the increase in I-cache average access time plus one-half the increase in D-cache access time, or $1.04 + 0.5 \times 0.13 = 1.11$ times longer. This result means that way selection has 0.90 of the performance of a standard four-way cache. Thus way selection improves performance per joule very slightly by a ratio of $0.90/0.88 = 1.02$. This optimization is best used where power rather than performance is the key objective.

Third Optimization: Pipelined Access and Multibanked Caches to Increase Bandwidth

These optimizations increase cache bandwidth either by pipelining the cache access or by widening the cache with multiple banks to allow multiple accesses per clock; these optimizations are the dual to the superpipelined and superscalar approaches to increasing instruction throughput. These optimizations are primarily targeted at L1, where access bandwidth constrains instruction throughput. Multiple banks are also used in L2 and L3 caches, but primarily as a power-management technique.

Pipelining L1 allows a higher clock cycle, at the cost of increased latency. For example, the pipeline for the instruction cache access for Intel Pentium processors in the mid-1990s took 1 clock cycle; for the Pentium Pro through Pentium III in the mid-1990s through 2000, it took 2 clock cycles; and for the Pentium 4, which became available in 2000, and the current Intel Core i7, it takes 4 clock cycles. Pipelining the instruction cache effectively increases the number of pipeline stages,

Block address	Bank 0	Block address	Bank 1	Block address	Bank 2	Block address	Bank 3
0		1		2		3	
4		5		6		7	
8		9		10		11	
12		13		14		15	

Figure 2.10 Four-way interleaved cache banks using block addressing. Assuming 64 bytes per block, each of these addresses would be multiplied by 64 to get byte addressing.

leading to a greater penalty on mispredicted branches. Correspondingly, pipelining the data cache leads to more clock cycles between issuing the load and using the data (see [Chapter 3](#)). Today, all processors use some pipelining of L1, if only for the simple case of separating the access and hit detection, and many high-speed processors have three or more levels of cache pipelining.

It is easier to pipeline the instruction cache than the data cache because the processor can rely on high performance branch prediction to limit the latency effects. Many superscalar processors can issue and execute more than one memory reference per clock (allowing a load or store is common, and some processors allow multiple loads). To handle multiple data cache accesses per clock, we can divide the cache into independent banks, each supporting an independent access. Banks were originally used to improve performance of main memory and are now used inside modern DRAM chips as well as with caches. The Intel Core i7 has four banks in L1 (to support up to 2 memory accesses per clock).

Clearly, banking works best when the accesses naturally spread themselves across the banks, so the mapping of addresses to banks affects the behavior of the memory system. A simple mapping that works well is to spread the addresses of the block sequentially across the banks, which is called *sequential interleaving*. For example, if there are four banks, bank 0 has all blocks whose address modulo 4 is 0, bank 1 has all blocks whose address modulo 4 is 1, and so on. [Figure 2.10](#) shows this interleaving. Multiple banks also are a way to reduce power consumption in both caches and DRAM.

Multiple banks are also useful in L2 or L3 caches, but for a different reason. With multiple banks in L2, we can handle more than one outstanding L1 miss, if the banks do not conflict. This is a key capability to support nonblocking caches, our next optimization. The L2 in the Intel Core i7 has eight banks, while Arm Cortex processors have used L2 caches with 1–4 banks. As mentioned earlier, multibanking can also reduce energy consumption.

Fourth Optimization: Nonblocking Caches to Increase Cache Bandwidth

For pipelined computers that allow out-of-order execution (discussed in [Chapter 3](#)), the processor need not stall on a data cache miss. For example, the processor could

continue fetching instructions from the instruction cache while waiting for the data cache to return the missing data. A *nonblocking cache* or *lockup-free cache* escalates the potential benefits of such a scheme by allowing the data cache to continue to supply cache hits during a miss. This “hit under miss” optimization reduces the effective miss penalty by being helpful during a miss instead of ignoring the requests of the processor. A subtle and complex option is that the cache may further lower the effective miss penalty if it can overlap multiple misses: a “hit under multiple miss” or “miss under miss” optimization. The second option is beneficial only if the memory system can service multiple misses; most high-performance processors (such as the Intel Core processors) usually support both, whereas many lower-end processors provide only limited nonblocking support in L2.

To examine the effectiveness of nonblocking caches in reducing the cache miss penalty, Farkas and Jouppi (1994) did a study assuming 8 KiB caches with a 14-cycle miss penalty (appropriate for the early 1990s). They observed a reduction in the effective miss penalty of 20% for the SPECINT92 benchmarks and 30% for the SPECFP92 benchmarks when allowing one hit under miss.

Li et al. (2011) updated this study to use a multilevel cache, more modern assumptions about miss penalties, and the larger and more demanding SPEC CPU2006 benchmarks. The study was done assuming a model based on a single core of an Intel i7 (see Section 2.6) running the SPEC CPU2006 benchmarks. Figure 2.11 shows the reduction in data cache access latency when allowing 1, 2, and 64 hits under a miss; the caption describes further details of the memory system. The larger caches and the addition of an L3 cache since the earlier study have reduced the benefits with the SPECINT2006 benchmarks showing an average reduction in cache latency of about 9% and the SPEC FP2006 benchmarks about 12.5%.

Example Which is more important for floating-point programs: two-way set associativity or hit under one miss for the primary data caches? What about integer programs? Assume the following average miss rates for 32 KiB data caches: 5.2% for floating-point programs with a direct-mapped cache, 4.9% for the programs with a two-way set associative cache, 3.5% for integer programs with a direct-mapped cache, and 3.2% for integer programs with a two-way set associative cache. Assume the miss penalty to L2 is 10 cycles, and the L2 misses and penalties are the same.

Answer For floating-point programs, the average memory stall times are

$$\text{Miss rate}_{\text{DM}} \times \text{Miss penalty} = 5.2\% \times 10 = 0.52$$

$$\text{Miss rate}_{2\text{-way}} \times \text{Miss penalty} = 4.9\% \times 10 = 0.49$$

The cache access latency (including stalls) for two-way associativity is 0.49/0.52 or 94% of direct-mapped cache. Figure 2.11 caption indicates that a hit under one miss reduces the average data cache access latency for floating-point programs to 87.5% of a blocking cache. Therefore, for floating-point programs, the

Figure 2.11 The effectiveness of a nonblocking cache is evaluated by allowing 1, 2, or 64 hits under a cache miss with 9 SPECINT (on the left) and 9 SPECFP (on the right) benchmarks. The data memory system modeled after the Intel i7 consists of a 32 KiB L1 cache with a four-cycle access latency. The L2 cache (shared with instructions) is 256 KiB with a 10-clock cycle access latency. The L3 is 2 MiB and a 36-cycle access latency. All the caches are eight-way set associative and have a 64-byte block size. Allowing one hit under miss reduces the miss penalty by 9% for the integer benchmarks and 12.5% for the floating point. Allowing a second hit improves these results to 10% and 16%, and allowing 64 results in little additional improvement.

direct-mapped data cache supporting one hit under one miss gives better performance than a two-way set-associative cache that blocks on a miss.

For integer programs, the calculation is

$$\text{Miss rate}_{\text{DM}} \times \text{Miss penalty} = 3.5\% \times 10 = 0.35$$

$$\text{Miss rate}_{\text{2-way}} \times \text{Miss penalty} = 3.2\% \times 10 = 0.32$$

The data cache access latency of a two-way set associative cache is thus $0.32/0.35$ or 91% of direct-mapped cache, while the reduction in access latency when allowing a hit under one miss is 9%, making the two choices about equal.

The real difficulty with performance evaluation of nonblocking caches is that a cache miss does not necessarily stall the processor. In this case, it is difficult to judge the impact of any single miss and thus to calculate the average memory access time. The effective miss penalty is not the sum of the misses but the nonoverlapped time that the processor is stalled. The benefit of nonblocking caches is complex, as it depends upon the miss penalty when there are multiple misses, the memory reference pattern, and how many instructions the processor can execute with a miss outstanding.

In general, out-of-order processors are capable of hiding much of the miss penalty of an L1 data cache miss that hits in the L2 cache but are not capable

of hiding a significant fraction of a lower-level cache miss. Deciding how many outstanding misses to support depends on a variety of factors:

- The temporal and spatial locality in the miss stream, which determines whether a miss can initiate a new access to a lower-level cache or to memory.
- The bandwidth of the responding memory or cache.
- To allow more outstanding misses at the lowest level of the cache (where the miss time is the longest) requires supporting at least that many misses at a higher level, because the miss must initiate at the highest level cache.
- The latency of the memory system.

The following simplified example illustrates the key idea.

Example Assume a main memory access time of 36 ns and a memory system capable of a sustained transfer rate of 16 GiB/s. If the block size is 64 bytes, what is the maximum number of outstanding misses we need to support assuming that we can maintain the peak bandwidth given the request stream and that accesses never conflict. If the probability of a reference colliding with one of the previous four is 50%, and we assume that the access has to wait until the earlier access completes, estimate the number of maximum outstanding references. For simplicity, ignore the time between misses.

Answer In the first case, assuming that we can maintain the peak bandwidth, the memory system can support $(16 \times 10^9)/64 = 250$ million references per second. Because each reference takes 36 ns, we can support $250 \times 10^6 \times 36 \times 10^{-9} = 9$ references. If the probability of a collision is greater than 0, then we need more outstanding references, because we cannot start work on those colliding references; the memory system needs more independent references, not fewer! To approximate, we can simply assume that half the memory references do not have to be issued to the memory. This means that we must support twice as many outstanding references, or 18.

In Li, Chen, Brockman, and Jouppi's study, they found that the reduction in CPI for the integer programs was about 7% for one hit under miss and about 12.7% for 64. For the floating-point programs, the reductions were 12.7% for one hit under miss and 17.8% for 64. These reductions track fairly closely the reductions in the data cache access latency shown in [Figure 2.11](#).

Implementing a Nonblocking Cache

Although nonblocking caches have the potential to improve performance, they are nontrivial to implement. Two initial types of challenges arise: arbitrating contention between hits and misses, and tracking outstanding misses so that we know when loads or stores can proceed. Consider the first problem. In a blocking cache, misses cause the processor to stall and no further accesses to the cache will occur

until the miss is handled. In a nonblocking cache, however, hits can collide with misses returning from the next level of the memory hierarchy. If we allow multiple outstanding misses, which almost all recent processors do, it is even possible for misses to collide. These collisions must be resolved, usually by first giving priority to hits over misses, and second by ordering colliding misses (if they can occur).

The second problem arises because we need to track multiple outstanding misses. In a blocking cache, we always know which miss is returning, because only one can be outstanding. In a nonblocking cache, this is rarely true. At first glance, you might think that misses always return in order, so that a simple queue could be kept to match a returning miss with the longest outstanding request. Consider, however, a miss that occurs in L1. It may generate either a hit or miss in L2; if L2 is also nonblocking, then the order in which misses are returned to L1 will not necessarily be the same as the order in which they originally occurred. Multi-core and other multiprocessor systems that have nonuniform cache access times also introduce this complication.

When a miss returns, the processor must know which load or store caused the miss, so that instruction can now go forward; and it must know where in the cache the data should be placed (as well as the setting of tags for that block). In recent processors, this information is kept in a set of registers, typically called the *Miss Status Handling Registers (MSHRs)*. If we allow n outstanding misses, there will be n MSHRs, each holding the information about where a miss goes in the cache and the value of any tag bits for that miss, as well as the information indicating which load or store caused the miss (in the next chapter, you will see how this is tracked). Thus, when a miss occurs, we allocate an MSHR for handling that miss, enter the appropriate information about the miss, and tag the memory request with the index of the MSHR. The memory system uses that tag when it returns the data, allowing the cache system to transfer the data and tag information to the appropriate cache block and “notify” the load or store that generated the miss that the data is now available and that it can resume operation. Nonblocking caches clearly require extra logic and thus have some cost in energy. It is difficult, however, to assess their energy costs exactly because they may reduce stall time, thereby decreasing execution time and resulting energy consumption.

In addition to the preceding issues, multiprocessor memory systems, whether within a single chip or on multiple chips, must also deal with complex implementation issues related to memory coherency and consistency. Also, because cache misses are no longer atomic (because the request and response are split and may be interleaved among multiple requests), there are possibilities for deadlock. For the interested reader, Section I.7 in online Appendix I deals with these issues in detail.

Fifth Optimization: Critical Word First and Early Restart to Reduce Miss Penalty

This technique is based on the observation that the processor normally needs just one word of the block at a time. This strategy is impatience: don’t wait for the full

block to be loaded before sending the requested word and restarting the processor. Here are two specific strategies:

- *Critical word first*—Request the missed word first from memory and send it to the processor as soon as it arrives; let the processor continue execution while filling the rest of the words in the block.
- *Early restart*—Fetch the words in normal order, but as soon as the requested word of the block arrives, send it to the processor and let the processor continue execution.

Generally, these techniques only benefit designs with large cache blocks because the benefit is low unless blocks are large. Note that caches normally continue to satisfy accesses to other blocks while the rest of the block is being filled.

However, given spatial locality, there is a good chance that the next reference is to the rest of the block. Just as with nonblocking caches, the miss penalty is not simple to calculate. When there is a second request in critical word first, the effective miss penalty is the nonoverlapped time from the reference until the second piece arrives. The benefits of critical word first and early restart depend on the size of the block and the likelihood of another access to the portion of the block that has not yet been fetched. For example, for SPECint2006 running on the i7 6700, which uses early restart and critical word first, there is more than one reference made to a block with an outstanding miss (1.23 references on average with a range from 0.5 to 3.0). We explore the performance of the i7 memory hierarchy in more detail in [Section 2.6](#).

Sixth Optimization: Merging Write Buffer to Reduce Miss Penalty

Write-through caches rely on write buffers, as all stores must be sent to the next lower level of the hierarchy. Even write-back caches use a simple buffer when a block is replaced. If the write buffer is empty, the data and the full address are written in the buffer, and the write is finished from the processor's perspective; the processor continues working while the write buffer prepares to write the word to memory. If the buffer contains other modified blocks, the addresses can be checked to see if the address of the new data matches the address of a valid write buffer entry. If so, the new data are combined with that entry. *Write merging* is the name of this optimization. The Intel Core i7, among many others, uses write merging.

If the buffer is full and there is no address match, the cache (and processor) must wait until the buffer has an empty entry. This optimization uses the memory more efficiently because multiword writes are usually faster than writes performed one word at a time. [Skadron and Clark \(1997\)](#) found that even a merging four-entry write buffer generated stalls that led to a 5%–10% performance loss.

Write address	V	V	V	V
100	1	Mem[100]	0	0
108	1	Mem[108]	0	0
116	1	Mem[116]	0	0
124	1	Mem[124]	0	0

Write address	V	V	V	V
100	1	Mem[100]	1	Mem[108]
	0		0	
	0		0	
	0		0	

Figure 2.12 In this illustration of write merging, the write buffer on top does not use write merging while the write buffer on the bottom does. The four writes are merged into a single buffer entry with write merging; without it, the buffer is full even though three-fourths of each entry is wasted. The buffer has four entries, and each entry holds four 64-bit words. The address for each entry is on the left, with a valid bit (V) indicating whether the next sequential 8 bytes in this entry are occupied. (Without write merging, the words to the right in the upper part of the figure would be used only for instructions that wrote multiple words at the same time.)

The optimization also reduces stalls because of the write buffer being full. [Figure 2.12](#) shows a write buffer with and without write merging. Assume we had four entries in the write buffer, and each entry could hold four 64-bit words. Without this optimization, four stores to sequential addresses would fill the buffer at one word per entry, even though these four words when merged fit exactly within a single entry of the write buffer.

Note that input/output device registers are often mapped into the physical address space. These I/O addresses *cannot* allow write merging because separate I/O registers may not act like an array of words in memory. For example, they may require one address and data word per I/O register rather than use multiword writes using a single address. These side effects are typically implemented by marking the pages as requiring nonmerging write through by the caches.

Seventh Optimization: Compiler Optimizations to Reduce Miss Rate

Thus far, our techniques have required changing the hardware. This next technique reduces miss rates without any hardware changes.

This magical reduction comes from optimized software—the hardware designer’s favorite solution! The increasing performance gap between processors and main memory has inspired compiler writers to scrutinize the memory hierarchy to see if compile time optimizations can improve performance. Once again, research is split between improvements in instruction misses and improvements in data misses. The optimizations presented next are found in many modern compilers.

Loop Interchange

Some programs have nested loops that access data in memory in nonsequential order. Simply exchanging the nesting of the loops can make the code access the data in the order in which they are stored. Assuming the arrays do not fit in the cache, this technique reduces misses by improving spatial locality; reordering maximizes use of data in a cache block before they are discarded. For example, if x is a two-dimensional array of size $[5000, 100]$ allocated so that $x[i, j]$ and $x[i, j + 1]$ are adjacent (an order called *row major* because the array is laid out by rows), then the two pieces of the following code show how the accesses can be optimized:

```
/* Before */
for (j = 0; j < 100; j = j + 1)
    for (i = 0; i < 5000; i = i + 1)
        x[i][j] = 2 * x[i][j];

/* After */
for (i = 0; i < 5000; i = i + 1)
    for (j = 0; j < 100; j = j + 1)
        x[i][j] = 2 * x[i][j];
```

The original code would skip through memory in strides of 100 words, while the revised version accesses all the words in one cache block before going to the next block. This optimization improves cache performance without affecting the number of instructions executed.

Blocking

This optimization improves temporal locality to reduce misses. We are again dealing with multiple arrays, with some arrays accessed by rows and some by columns. Storing the arrays row by row (*row major order*) or column by column (*column major order*) does not solve the problem because both rows and columns are used in every loop iteration. Such orthogonal accesses mean that transformations such as loop interchange still leave plenty of room for improvement.

Figure 2.13 A snapshot of the three arrays x , y , and z when $N=6$ and $i=1$. The age of accesses to the array elements is indicated by shade: white means not yet touched, light means older accesses, and dark means newer accesses. The elements of y and z are read repeatedly to calculate new elements of x . The variables i , j , and k are shown along the rows or columns used to access the arrays.

Instead of operating on entire rows or columns of an array, blocked algorithms operate on submatrices or *blocks*. The goal is to maximize accesses to the data loaded into the cache before the data are replaced. The following code example, which performs matrix multiplication, helps motivate the optimization:

```
/* Before */
for (i = 0; i < N; i = i + 1)
    for (j = 0; j < N; j = j + 1)
        { r = 0;
          for (k = 0; k < N; k = k + 1)
              r = r + y[i][k]*z[k][j];
          x[i][j] = r;
        };
```

The two inner loops read all N -by- N elements of z , read the same N elements in a row of y repeatedly, and write one row of N elements of x . Figure 2.13 gives a snapshot of the accesses to the three arrays. A dark shade indicates a recent access, a light shade indicates an older access, and white means not yet accessed.

The number of capacity misses clearly depends on N and the size of the cache. If it can hold all three N -by- N matrices, then all is well, provided there are no cache conflicts. If the cache can hold one N -by- N matrix and one row of N , then at least the i th row of y and the array z may stay in the cache. Less than that and misses may occur for both x and z . In the worst case, there would be $2N^3 + N^2$ memory words accessed for N^3 operations.

To ensure that the elements being accessed can fit in the cache, the original code is changed to compute on a submatrix of size B by B . Two inner loops now compute in steps of size B rather than the full length of x and z . B is called the *blocking factor*. (Assume x is initialized to zero.)

```

/* After */
for (jj = 0; jj < N; jj = jj + B)
for (kk = 0; kk < N; kk = kk + B)
for (i = 0; i < N; i = i + 1)
    for (j = jj; j < min(jj + B, N); j = j + 1)
        {r = 0;
         for (k = kk; k < min(kk + B, N); k = k + 1)
             r = r + y[i][k]*z[k][j];
         x[i][j] = x[i][j] + r;
        };

```

Figure 2.14 illustrates the accesses to the three arrays using blocking. Looking only at capacity misses, the total number of memory words accessed is $2N^3/B + N^2$. This total is an improvement by an approximate factor of B . Therefore blocking exploits a combination of spatial and temporal locality, because y benefits from spatial locality and z benefits from temporal locality. Although our example uses a square block ($B \times B$), we could also use a rectangular block, which would be necessary if the matrix were not square.

Although we have aimed at reducing cache misses, blocking can also be used to help register allocation. By taking a small blocking size such that the block can be held in registers, we can minimize the number of loads and stores in the program.

As we shall see in Section 4.8 of Chapter 4, cache blocking is absolutely necessary to get good performance from cache-based processors running applications using matrices as the primary data structure.

Eighth Optimization: Hardware Prefetching of Instructions and Data to Reduce Miss Penalty or Miss Rate

Nonblocking caches effectively reduce the miss penalty by overlapping execution with memory access. Another approach is to prefetch items before the processor requests them. Both instructions and data can be prefetched, either directly into

Figure 2.14 The age of accesses to the arrays x , y , and z when $B = 3$. Note that, in contrast to Figure 2.13, a smaller number of elements is accessed.

the caches or into an external buffer that can be more quickly accessed than main memory.

Instruction prefetch is frequently done in hardware outside of the cache. Typically, the processor fetches two blocks on a miss: the requested block and the next consecutive block. The requested block is placed in the instruction cache when it returns, and the prefetched block is placed in the instruction stream buffer. If the requested block is present in the instruction stream buffer, the original cache request is canceled, the block is read from the stream buffer, and the next prefetch request is issued.

A similar approach can be applied to data accesses (Jouppi, 1990). Palacharla and Kessler (1994) looked at a set of scientific programs and considered multiple stream buffers that could handle either instructions or data. They found that eight stream buffers could capture 50%–70% of all misses from a processor with two 64 KiB four-way set associative caches, one for instructions and the other for data.

The Intel Core i7 supports hardware prefetching into both L1 and L2 with the most common case of prefetching being accessing the next line. Some earlier Intel processors used more aggressive hardware prefetching, but that resulted in reduced performance for some applications, causing some sophisticated users to turn off the capability.

Figure 2.15 shows the overall performance improvement for a subset of SPEC2000 programs when hardware prefetching is turned on. Note that this figure

Figure 2.15 Speedup because of hardware prefetching on Intel Pentium 4 with hardware prefetching turned on for 2 of 12 SPECint2000 benchmarks and 9 of 14 SPECfp2000 benchmarks. Only the programs that benefit the most from prefetching are shown; prefetching speeds up the missing 15 SPEC CPU benchmarks by less than 15% (Boggs et al., 2004).

includes only 2 of 12 integer programs, while it includes the majority of the SPECCPU floating-point programs. We will return to our evaluation of prefetching on the i7 in [Section 2.6](#).

Prefetching relies on utilizing memory bandwidth that otherwise would be unused, but if it interferes with demand misses, it can actually lower performance. Help from compilers can reduce useless prefetching. When prefetching works well, its impact on power is negligible. When prefetched data are not used or useful data are displaced, prefetching will have a very negative impact on power.

Ninth Optimization: Compiler-Controlled Prefetching to Reduce Miss Penalty or Miss Rate

An alternative to hardware prefetching is for the compiler to insert prefetch instructions to request data before the processor needs it. There are two flavors of prefetch:

- *Register prefetch* loads the value into a register.
- *Cache prefetch* loads data only into the cache and not the register.

Either of these can be *faulting* or *nonfaulting*; that is, the address does or does not cause an exception for virtual address faults and protection violations. Using this terminology, a normal load instruction could be considered a “faulting register prefetch instruction.” Nonfaulting prefetches simply turn into no-ops if they would normally result in an exception, which is what we want.

The most effective prefetch is “semantically invisible” to a program: it doesn’t change the contents of registers and memory, *and* it cannot cause virtual memory faults. Most processors today offer nonfaulting cache prefetches. This section assumes nonfaulting cache prefetch, also called *nonbinding* prefetch.

Prefetching makes sense only if the processor can proceed while prefetching the data; that is, the caches do not stall but continue to supply instructions and data while waiting for the prefetched data to return. As you would expect, the data cache for such computers is normally nonblocking.

Like hardware-controlled prefetching, the goal is to overlap execution with the prefetching of data. Loops are the important targets because they lend themselves to prefetch optimizations. If the miss penalty is small, the compiler just unrolls the loop once or twice, and it schedules the prefetches with the execution. If the miss penalty is large, it uses software pipelining (see Appendix H) or unrolls many times to prefetch data for a future iteration.

Issuing prefetch instructions incurs an instruction overhead, however, so compilers must take care to ensure that such overheads do not exceed the benefits. By concentrating on references that are likely to be cache misses, programs can avoid unnecessary prefetches while improving average memory access time significantly.

Example For the following code, determine which accesses are likely to cause data cache misses. Next, insert prefetch instructions to reduce misses. Finally, calculate the number of prefetch instructions executed and the misses avoided by prefetching. Let's assume we have an 8 KiB direct-mapped data cache with 16-byte blocks, and it is a write-back cache that does write allocate. The elements of *a* and *b* are 8 bytes long because they are double-precision floating-point arrays. There are 3 rows and 100 columns for *a* and 101 rows and 3 columns for *b*. Let's also assume they are not in the cache at the start of the program.

```
for (i = 0; i < 3; i = i + 1)
    for (j = 0; j < 100; j = j + 1)
        a[i][j] = b[j][0] * b[j + 1][0];
```

Answer The compiler will first determine which accesses are likely to cause cache misses; otherwise, we will waste time on issuing prefetch instructions for data that would be hits. Elements of *a* are written in the order that they are stored in memory, so *a* will benefit from spatial locality: The even values of *j* will miss and the odd values will hit. Because *a* has 3 rows and 100 columns, its accesses will lead to $3 \times (100/2)$, or 150 misses.

The array *b* does not benefit from spatial locality because the accesses are not in the order it is stored. The array *b* does benefit twice from temporal locality: the same elements are accessed for each iteration of *i*, and each iteration of *j* uses the same value of *b* as the last iteration. Ignoring potential conflict misses, the misses because of *b* will be for *b*[*j*+1][0] accesses when *i*=0, and also the first access to *b*[*j*][0] when *j*=0. Because *j* goes from 0 to 99 when *i*=0, accesses to *b* lead to 100+1, or 101 misses.

Thus this loop will miss the data cache approximately 150 times for *a* plus 101 times for *b*, or 251 misses.

To simplify our optimization, we will not worry about prefetching the first accesses of the loop. These may already be in the cache, or we will pay the miss penalty of the first few elements of *a* or *b*. Nor will we worry about suppressing the prefetches at the end of the loop that try to prefetch beyond the end of *a* (*a*[*i*][100] ... *a*[*i*][106]) and the end of *b* (*b*[101][0] ... *b*[107][0]). If these were faulting prefetches, we could not take this luxury. Let's assume that the miss penalty is so large we need to start prefetching at least, say, seven iterations in advance. (Stated alternatively, we assume prefetching has no benefit until the eighth iteration.) We underline the changes to the preceding code needed to add prefetching.

```
for (j = 0; j < 100; j = j + 1) {
    prefetch(b[j + 7][0]);
    /* b(j,0) for 7 iterations later */
    prefetch(a[0][j + 7]);
    /* a(0,j) for 7 iterations later */
    a[0][j] = b[j][0] * b[j + 1][0];}
```

```

for (i = 1; i < 3; i = i + 1)
    for (j = 0; j < 100; j = j + 1) {
        prefetch(a[i][j + 7]);
        /* a(i,j) for +7 iterations */
        a[i][j] = b[j][0] * b[j + 1][0];}

```

This revised code prefetches `a[i][7]` through `a[i][99]` and `b[7][0]` through `b[100][0]`, reducing the number of nonprefetched misses to

- 7 misses for elements `b[0][0]`, `b[1][0]`, ..., `b[6][0]` in the first loop
- 4 misses ($\lceil 7/2 \rceil$) for elements `a[0][0]`, `a[0][1]`, ..., `a[0][6]` in the first loop (spatial locality reduces misses to 1 per 16-byte cache block)
- 4 misses ($\lceil 7/2 \rceil$) for elements `a[1][0]`, `a[1][1]`, ..., `a[1][6]` in the second loop
- 4 misses ($\lceil 7/2 \rceil$) for elements `a[2][0]`, `a[2][1]`, ..., `a[2][6]` in the second loop

or a total of 19 nonprefetched misses. The cost of avoiding 232 cache misses is executing 400 prefetch instructions, likely a good trade-off.

Example Calculate the time saved in the preceding example. Ignore instruction cache misses and assume there are no conflict or capacity misses in the data cache. Assume that prefetches can overlap with each other and with cache misses, thereby transferring at the maximum memory bandwidth. Here are the key loop times ignoring cache misses: the original loop takes 7 clock cycles per iteration, the first prefetch loop takes 9 clock cycles per iteration, and the second prefetch loop takes 8 clock cycles per iteration (including the overhead of the outer for loop). A miss takes 100 clock cycles.

Answer The original doubly nested loop executes the multiply 3×100 or 300 times. Because the loop takes 7 clock cycles per iteration, the total is 300×7 or 2100 clock cycles plus cache misses. Cache misses add 251×100 or 25,100 clock cycles, giving a total of 27,200 clock cycles. The first prefetch loop iterates 100 times; at 9 clock cycles per iteration the total is 900 clock cycles plus cache misses. Now add 11×100 or 1100 clock cycles for cache misses, giving a total of 2000. The second loop executes 2×100 or 200 times, and at 8 clock cycles per iteration, it takes 1600 clock cycles plus 8×100 or 800 clock cycles for cache misses. This gives a total of 2400 clock cycles. From the prior example, we know that this code executes 400 prefetch instructions during the $2000 + 2400$ or 4400 clock cycles to execute these two loops. If we assume that the prefetches are completely overlapped with the rest of the execution, then the prefetch code is $27,200/4400$, or 6.2 times faster.

Although array optimizations are easy to understand, modern programs are more likely to use pointers. Luk and Mowry (1999) have demonstrated that compiler-based prefetching can sometimes be extended to pointers as well. Of 10 programs with recursive data structures, prefetching all pointers when a node is visited improved performance by 4%–31% in half of the programs. On the other hand, the remaining programs were still within 2% of their original performance. The issue is both whether prefetches are to data already in the cache and whether they occur early enough for the data to arrive by the time it is needed.

Many processors support instructions for cache prefetch, and high-end processors (such as the Intel Core i7) often also do some type of automated prefetch in hardware.

Tenth Optimization: Using HBM to Extend the Memory Hierarchy

Because most general-purpose processors in servers will likely want more memory than can be packaged with HBM packaging, it has been proposed that the in-package DRAMs be used to build massive L4 caches, with upcoming technologies ranging from 128 MiB to 1 GiB and more, considerably more than current on-chip L3 caches. Using such large DRAM-based caches raises an issue: where do the tags reside? That depends on the number of tags. Suppose we were to use a 64B block size; then a 1 GiB L4 cache requires 96 MiB of tags—far more static memory than exists in the caches on the CPU. Increasing the block size to 4 KiB, yields a dramatically reduced tag store of 256 K entries or less than 1 MiB total storage, which is probably acceptable, given L3 caches of 4–16 MiB or more in next-generation, multicore processors. Such large block sizes, however, have two major problems.

First, the cache may be used inefficiently when content of many blocks are not needed; this is called the *fragmentation problem*, and it also occurs in virtual memory systems. Furthermore, transferring such large blocks is inefficient if much of the data is unused. Second, because of the large block size, the number of distinct blocks held in the DRAM cache is much lower, which can result in more misses, especially for conflict and consistency misses.

One partial solution to the first problem is to add *subblocking*. *Subblocking* allow parts of the block to be invalid, requiring that they be fetched on a miss. Subblocking, however, does nothing to address the second problem.

The tag storage is the major drawback for using a smaller block size. One possible solution for that difficulty is to store the tags for L4 in the HBM. At first glance this seems unworkable, because it requires two accesses to DRAM for each L4 access: one for the tags and one for the data itself. Because of the long access time for random DRAM accesses, typically 100 or more processor clock cycles, such an approach had been discarded. Loh and Hill (2011) proposed a clever solution to this problem: place the tags and the data in the same row in the HBM SDRAM. Although opening the row (and eventually closing it) takes a large amount of time, the CAS latency to access a different part of the row is about one-third the new row access time. Thus we can access the tag portion of the block first, and if it is a hit,

then use a column access to choose the correct word. Loh and Hill (L-H) have proposed organizing the L4 HBM cache so that each SDRAM row consists of a set of tags (at the head of the block) and 29 data segments, making a 29-way set associative cache. When L4 is accessed, the appropriate row is opened and the tags are read; a hit requires one more column access to get the matching data.

Qureshi and Loh (2012) proposed an improvement called an *alloy cache* that reduces the hit time. An *alloy cache* molds the tag and data together and uses a direct mapped cache structure. This allows the L4 access time to be reduced to a single HBM cycle by directly indexing the HBM cache and doing a burst transfer of both the tag and data. Figure 2.16 shows the hit latency for the alloy cache, the L-H scheme, and SRAM based tags. The alloy cache reduces hit time by more than a factor of 2 versus the L-H scheme, in return for an increase in the miss rate by a factor of 1.1–1.2. The choice of benchmarks is explained in the caption.

Unfortunately, in both schemes, misses require two full DRAM accesses: one to get the initial tag and a follow-on access to the main memory (which is even

Figure 2.16 Average hit time latency in clock cycles for the L-H scheme, a currently-impractical scheme using SRAM for the tags, and the alloy cache organization. In the SRAM case, we assume the SRAM is accessible in the same time as L3 and that it is checked before L4 is accessed. The average hit latencies are 43 (alloy cache), 67 (SRAM tags), and 107 (L-H). The 10 SPECCPU2006 benchmarks used here are the most memory-intensive ones; each of them would run twice as fast if L3 were perfect.

slower). If we could speed up the miss detection, we could reduce the miss time. Two different solutions have been proposed to solve this problem: one uses a map that keeps track of the blocks in the cache (not the location of the block, just whether it is present); the other uses a memory access predictor that predicts likely misses using history prediction techniques, similar to those used for global branch prediction (see the next chapter). It appears that a small predictor can predict likely misses with high accuracy, leading to an overall lower miss penalty.

Figure 2.17 shows the speedup obtained on SPECrate for the memory-intensive benchmarks used in Figure 2.16. The alloy cache approach outperforms the LH scheme and even the impractical SRAM tags, because the combination of a fast access time for the miss predictor and good prediction results lead to a shorter time to predict a miss, and thus a lower miss penalty. The alloy cache performs close to the Ideal case, an L4 with perfect miss prediction and minimal hit time.

Figure 2.17 Performance speedup running the SPECrate benchmark for the LH scheme, an SRAM tag scheme, and an ideal L4 (Ideal); a speedup of 1 indicates no improvement with the L4 cache, and a speedup of 2 would be achievable if L4 were perfect and took no access time. The 10 memory-intensive benchmarks are used with each benchmark run eight times. The accompanying miss prediction scheme is used. The Ideal case assumes that only the 64-byte block requested in L4 needs to be accessed and transferred and that prediction accuracy for L4 is perfect (i.e., all misses are known at zero cost).

HBM is likely to have widespread use in a variety of different configurations, from containing the entire memory system for some high-performance, special-purpose systems to use as an L4 cache for larger server configurations.

Cache Optimization Summary

The techniques to improve hit time, bandwidth, miss penalty, and miss rate generally affect the other components of the average memory access equation as well as the complexity of the memory hierarchy. [Figure 2.18](#) summarizes these techniques and estimates the impact on complexity, with + meaning that the technique

Technique	Hit time	Bandwidth	Miss penalty	Miss rate	Power consumption	Hardware cost/complexity	Comment
Small and simple caches	+			–	+	0	Trivial; widely used
Way-predicting caches	+				+	1	Used in Pentium 4
Pipelined & banked caches	–	+				1	Widely used
Nonblocking caches		+	+			3	Widely used
Critical word first and early restart			+			2	Widely used
Merging write buffer			+			1	Widely used with write through
Compiler techniques to reduce cache misses				+		0	Software is a challenge, but many compilers handle common linear algebra calculations
Hardware prefetching of instructions and data			+	+	–	2 instr., 3 data	Most provide prefetch instructions; modern high-end processors also automatically prefetch in hardware
Compiler-controlled prefetching			+	+		3	Needs nonblocking cache; possible instruction overhead; in many CPUs
HBM as additional level of cache		+/-	–	+	+	3	Depends on new packaging technology. Effects depend heavily on hit rate improvements

Figure 2.18 Summary of 10 advanced cache optimizations showing impact on cache performance, power consumption, and complexity. Although generally a technique helps only one factor, prefetching can reduce misses if done sufficiently early; if not, it can reduce miss penalty. + means that the technique improves the factor, – means it hurts that factor, and blank means it has no impact. The complexity measure is subjective, with 0 being the easiest and 3 being a challenge.

improves the factor, — meaning it hurts that factor, and blank meaning it has no impact. Generally, no technique helps more than one category.

2.4

Virtual Memory and Virtual Machines

A virtual machine is taken to be an efficient, isolated duplicate of the real machine. We explain these notions through the idea of a virtual machine monitor (VMM)... a VMM has three essential characteristics. First, the VMM provides an environment for programs which is essentially identical with the original machine; second, programs run in this environment show at worst only minor decreases in speed; and last, the VMM is in complete control of system resources.

Gerald Popek and Robert Goldberg,

“Formal requirements for virtualizable third generation architectures,”

Communications of the ACM (July 1974).

Section B.4 in [Appendix B](#) describes the key concepts in virtual memory. Recall that virtual memory allows the physical memory to be treated as a cache of secondary storage (which may be either disk or solid state). Virtual memory moves pages between the two levels of the memory hierarchy, just as caches move blocks between levels. Likewise, TLBs act as caches on the page table, eliminating the need to do a memory access every time an address is translated. Virtual memory also provides separation between processes that share one physical memory but have separate virtual address spaces. Readers should ensure that they understand both functions of virtual memory before continuing.

In this section, we focus on additional issues in protection and privacy between processes sharing the same processor. Security and privacy are two of the most vexing challenges for information technology in 2017. Electronic burglaries, often involving lists of credit card numbers, are announced regularly, and it’s widely believed that many more go unreported. Of course, such problems arise from programming errors that allow a cyberattack to access data it should be unable to access. Programming errors are a fact of life, and with modern complex software systems, they occur with significant regularity. Therefore both researchers and practitioners are looking for improved ways to make computing systems more secure. Although protecting information is not limited to hardware, in our view real security and privacy will likely involve innovation in computer architecture as well as in systems software.

This section starts with a review of the architecture support for protecting processes from each other via virtual memory. It then describes the added protection provided by virtual machines, the architecture requirements of virtual machines, and the performance of a virtual machine. As we will see in [Chapter 6](#), virtual machines are a foundational technology for cloud computing.

Protection via Virtual Memory

Page-based virtual memory, including a TLB that caches page table entries, is the primary mechanism that protects processes from each other. Sections B.4 and B.5 in [Appendix B](#) review virtual memory, including a detailed description of protection via segmentation and paging in the 80x86. This section acts as a quick review; if it's too quick, please refer to the denoted [Appendix B](#) sections.

Multiprogramming, where several programs running concurrently share a computer, has led to demands for protection and sharing among programs and to the concept of a *process*. Metaphorically, a process is a program's breathing air and living space—that is, a running program plus any state needed to continue running it. At any instant, it must be possible to switch from one process to another. This exchange is called a *process switch* or *context switch*.

The operating system and architecture join forces to allow processes to share the hardware yet not interfere with each other. To do this, the architecture must limit what a process can access when running a user process yet allow an operating system process to access more. At a minimum, the architecture must do the following:

1. Provide at least two modes, indicating whether the running process is a user process or an operating system process. This latter process is sometimes called a *kernel* process or a *supervisor* process.
2. Provide a portion of the processor state that a user process can use but not write. This state includes a user/supervisor mode bit, an exception enable/disable bit, and memory protection information. Users are prevented from writing this state because the operating system cannot control user processes if users can give themselves supervisor privileges, disable exceptions, or change memory protection.
3. Provide mechanisms whereby the processor can go from user mode to supervisor mode and vice versa. The first direction is typically accomplished by a *system call*, implemented as a special instruction that transfers control to a dedicated location in supervisor code space. The PC is saved from the point of the system call, and the processor is placed in supervisor mode. The return to user mode is like a subroutine return that restores the previous user/supervisor mode.
4. Provide mechanisms to limit memory accesses to protect the memory state of a process without having to swap the process to disk on a context switch.

[Appendix A](#) describes several memory protection schemes, but by far the most popular is adding protection restrictions to each page of virtual memory. Fixed-sized pages, typically 4 KiB, 16 KiB, or larger, are mapped from the virtual address space into physical address space via a page table. The protection restrictions are included in each page table entry. The protection restrictions might determine whether a user process can read this page, whether a user process can write to this page, and whether code can be executed from this page. In addition, a process can

neither read nor write a page if it is not in the page table. Because only the OS can update the page table, the paging mechanism provides total access protection.

Paged virtual memory means that every memory access logically takes at least twice as long, with one memory access to obtain the physical address and a second access to get the data. This cost would be far too dear. The solution is to rely on the principle of locality; if the accesses have locality, then the *address translations* for the accesses must also have locality. By keeping these address translations in a special cache, a memory access rarely requires a second access to translate the address. This special address translation cache is referred to as a TLB.

A TLB entry is like a cache entry where the tag holds portions of the virtual address and the data portion holds a physical page address, protection field, valid bit, and usually a use bit and a dirty bit. The operating system changes these bits by changing the value in the page table and then invalidating the corresponding TLB entry. When the entry is reloaded from the page table, the TLB gets an accurate copy of the bits.

Assuming the computer faithfully obeys the restrictions on pages and maps virtual addresses to physical addresses, it would seem that we are done. Newspaper headlines suggest otherwise.

The reason we're not done is that we depend on the accuracy of the operating system as well as the hardware. Today's operating systems consist of tens of millions of lines of code. Because bugs are measured in number per thousand lines of code, there are thousands of bugs in production operating systems. Flaws in the OS have led to vulnerabilities that are routinely exploited.

This problem and the possibility that not enforcing protection could be much more costly than in the past have led some to look for a protection model with a much smaller code base than the full OS, such as virtual machines.

Protection via Virtual Machines

An idea related to virtual memory that is almost as old are virtual machines (VMs). They were first developed in the late 1960s, and they have remained an important part of mainframe computing over the years. Although largely ignored in the domain of single-user computers in the 1980s and 1990s, they have recently gained popularity because of

- the increasing importance of isolation and security in modern systems;
- the failures in security and reliability of standard operating systems;
- the sharing of a single computer among many unrelated users, such as in a data center or cloud; and
- the dramatic increases in the raw speed of processors, which make the overhead of VMs more acceptable.

The broadest definition of VMs includes basically all emulation methods that provide a standard software interface, such as the Java VM. We are interested in

VMs that provide a complete system-level environment at the binary instruction set architecture (ISA) level. Most often, the VM supports the same ISA as the underlying hardware; however, it is also possible to support a different ISA, and such approaches are often employed when migrating between ISAs in order to allow software from the departing ISA to be used until it can be ported to the new ISA. Our focus here will be on VMs where the ISA presented by the VM and the underlying hardware match. Such VMs are called (operating) *system virtual machines*. IBM VM/370, VMware ESX Server, and Xen are examples. They present the illusion that the users of a VM have an entire computer to themselves, including a copy of the operating system. A single computer runs multiple VMs and can support a number of different operating systems (OSes). On a conventional platform, a single OS “owns” all the hardware resources, but with a VM, multiple OSes all share the hardware resources.

The software that supports VMs is called a *virtual machine monitor* (VMM) or *hypervisor*; the VMM is the heart of virtual machine technology. The underlying hardware platform is called the *host*, and its resources are shared among the *guest* VMs. The VMM determines how to map virtual resources to physical resources: A physical resource may be time-shared, partitioned, or even emulated in software. The VMM is much smaller than a traditional OS; the isolation portion of a VMM is perhaps only 10,000 lines of code.

In general, the cost of processor virtualization depends on the workload. User-level processor-bound programs, such as SPEC CPU2006, have zero virtualization overhead because the OS is rarely invoked, so everything runs at native speeds. Conversely, I/O-intensive workloads generally are also OS-intensive and execute many system calls (which doing I/O requires) and privileged instructions that can result in high virtualization overhead. The overhead is determined by the number of instructions that must be emulated by the VMM and how slowly they are emulated. Therefore, when the guest VMs run the same ISA as the host, as we assume here, the goal of the architecture and the VMM is to run almost all instructions directly on the native hardware. On the other hand, if the I/O-intensive workload is also *I/O-bound*, the cost of processor virtualization can be completely hidden by low processor utilization because it is often waiting for I/O.

Although our interest here is in VMs for improving protection, VMs provide two other benefits that are commercially significant:

1. *Managing software*—VMs provide an abstraction that can run the complete software stack, even including old operating systems such as DOS. A typical deployment might be some VMs running legacy OSes, many running the current stable OS release, and a few testing the next OS release.
2. *Managing hardware*—One reason for multiple servers is to have each application running with its own compatible version of the operating system on separate computers, as this separation can improve dependability. VMs allow these separate software stacks to run independently yet share hardware, thereby consolidating the number of servers. Another example is that most newer VMMs support migration of a running VM to a different computer, either to

balance load or to evacuate from failing hardware. The rise of cloud computing has made the ability to swap out an entire VM to another physical processor increasingly useful.

These two reasons are why cloud-based servers, such as Amazon's, rely on virtual machines.

Requirements of a Virtual Machine Monitor

What must a VM monitor do? It presents a software interface to guest software, it must isolate the state of guests from each other, and it must protect itself from guest software (including guest OSes). The qualitative requirements are

- Guest software should behave on a VM exactly as if it were running on the native hardware, except for performance-related behavior or limitations of fixed resources shared by multiple VMs.
- Guest software should not be able to directly change allocation of real system resources.

To “virtualize” the processor, the VMM must control just about everything—access to privileged state, address translation, I/O, exceptions and interrupts—even though the guest VM and OS currently running are temporarily using them.

For example, in the case of a timer interrupt, the VMM would suspend the currently running guest VM, save its state, handle the interrupt, determine which guest VM to run next, and then load its state. Guest VMs that rely on a timer interrupt are provided with a virtual timer and an emulated timer interrupt by the VMM.

To be in charge, the VMM must be at a higher privilege level than the guest VM, which generally runs in user mode; this also ensures that the execution of any privileged instruction will be handled by the VMM. The basic requirements of system virtual machines are almost identical to those for the previously mentioned paged virtual memory:

- At least two processor modes, system and user.
- A privileged subset of instructions that is available only in system mode, resulting in a trap if executed in user mode. All system resources must be controllable only via these instructions.

Instruction Set Architecture Support for Virtual Machines

If VMs are planned for during the design of the ISA, it's relatively easy to reduce both the number of instructions that must be executed by a VMM and how long it takes to emulate them. An architecture that allows the VM to execute directly on the hardware earns the title *virtualizable*, and the IBM 370 architecture proudly bears that label.

However, because VMs have been considered for desktop and PC-based server applications only fairly recently, most instruction sets were created without virtualization in mind. These culprits include 80x86 and most of the original RISC architectures, although the latter had fewer issues than the 80x86 architecture. Recent additions to the x86 architecture have attempted to remedy the earlier shortcomings, and RISC V explicitly includes support for virtualization.

Because the VMM must ensure that the guest system interacts only with virtual resources, a conventional guest OS runs as a user mode program on top of the VMM. Then, if a guest OS attempts to access or modify information related to hardware resources via a privileged instruction—for example, reading or writing the page table pointer—it will trap to the VMM. The VMM can then effect the appropriate changes to corresponding real resources.

Therefore, if any instruction that tries to read or write such sensitive information traps when executed in user mode, the VMM can intercept it and support a virtual version of the sensitive information as the guest OS expects.

In the absence of such support, other measures must be taken. A VMM must take special precautions to locate all problematic instructions and ensure that they behave correctly when executed by a guest OS, thereby increasing the complexity of the VMM and reducing the performance of running the VM. [Sections 2.5 and 2.7](#) give concrete examples of problematic instructions in the 80x86 architecture. One attractive extension allows the VM and the OS to operate at different privilege levels, each of which is distinct from the user level. By introducing an additional privilege level, some OS operations—e.g., those that exceed the permissions granted to a user program but do not require intervention by the VMM (because they cannot affect any other VM)—can execute directly without the overhead of trapping and invoking the VMM. The Xen design, which we examine shortly, makes use of three privilege levels.

Impact of Virtual Machines on Virtual Memory and I/O

Another challenge is virtualization of virtual memory, as each guest OS in every VM manages its own set of page tables. To make this work, the VMM separates the notions of *real* and *physical memory* (which are often treated synonymously) and makes real memory a separate, intermediate level between virtual memory and physical memory. (Some use the terms *virtual memory*, *physical memory*, and *machine memory* to name the same three levels.) The guest OS maps virtual memory to real memory via its page tables, and the VMM page tables map the guests' real memory to physical memory. The virtual memory architecture is specified either via page tables, as in IBM VM/370 and the 80x86, or via the TLB structure, as in many RISC architectures.

Rather than pay an extra level of indirection on every memory access, the VMM maintains a *shadow page table* that maps directly from the guest virtual address space to the physical address space of the hardware. By detecting all modifications to the guest's page table, the VMM can ensure that the shadow page table

entries being used by the hardware for translations correspond to those of the guest OS environment, with the exception of the correct physical pages substituted for the real pages in the guest tables. Therefore the VMM must trap any attempt by the guest OS to change its page table or to access the page table pointer. This is commonly done by write protecting the guest page tables and trapping any access to the page table pointer by a guest OS. As previously noted, the latter happens naturally if accessing the page table pointer is a privileged operation.

The IBM 370 architecture solved the page table problem in the 1970s with an additional level of indirection that is managed by the VMM. The guest OS keeps its page tables as before, so the shadow pages are unnecessary. AMD has implemented a similar scheme for its 80x86.

To virtualize the TLB in many RISC computers, the VMM manages the real TLB and has a copy of the contents of the TLB of each guest VM. To pull this off, any instructions that access the TLB must trap. TLBs with Process ID tags can support a mix of entries from different VMs and the VMM, thereby avoiding flushing of the TLB on a VM switch. Meanwhile, in the background, the VMM supports a mapping between the VMs' virtual Process IDs and the real Process IDs. Section L.7 of online Appendix L describes additional details.

The final portion of the architecture to virtualize is I/O. This is by far the most difficult part of system virtualization because of the increasing number of I/O devices attached to the computer *and* the increasing diversity of I/O device types. Another difficulty is the sharing of a real device among multiple VMs, and yet another comes from supporting the myriad of device drivers that are required, especially if different guest OSes are supported on the same VM system. The VM illusion can be maintained by giving each VM generic versions of each type of I/O device driver, and then leaving it to the VMM to handle real I/O.

The method for mapping a virtual-to-physical I/O device depends on the type of device. For example, physical disks are normally partitioned by the VMM to create virtual disks for guest VMs, and the VMM maintains the mapping of virtual tracks and sectors to the physical ones. Network interfaces are often shared between VMs in very short time slices, and the job of the VMM is to keep track of messages for the virtual network addresses to ensure that guest VMs receive only messages intended for them.

Extending the Instruction Set for Efficient Virtualization and Better Security

In the past 5–10 years, processor designers, including those at AMD and Intel (and to a lesser extent ARM), have introduced instruction set extensions to more efficiently support virtualization. Two primary areas of performance improvement have been in handling page tables and TLBs (the cornerstone of virtual memory) and in I/O, specifically handling interrupts and DMA. Virtual memory performance is enhanced by avoiding unnecessary TLB flushes and by using the nested page table mechanism, employed by IBM decades earlier, rather than a complete

set of shadow page tables (see Section L.7 in Appendix L). To improve I/O performance, architectural extensions are added that allow a device to directly use DMA to move data (eliminating a potential copy by the VMM) and allow device interrupts and commands to be handled by the guest OS directly. These extensions show significant performance gains in applications that are intensive either in their memory-management aspects or in the use of I/O.

With the broad adoption of public cloud systems for running critical applications, concerns have risen about security of data in such applications. Any malicious code that is able to access a higher privilege level than data that must be kept secure compromises the system. For example, if you are running a credit card processing application, you must be absolutely certain that malicious users cannot get access to the credit card numbers, even when they are using the same hardware and intentionally attack the OS or even the VMM. Through the use of virtualization, we can prevent accesses by an outside user to the data in a different VM, and this provides significant protection compared to a multiprogrammed environment. That might not be enough, however, if the attacker compromises the VMM or can find out information by observations in another VMM. For example, suppose the attacker penetrates the VMM; the attacker can then remap memory so as to access any portion of the data.

Alternatively, an attack might rely on a Trojan horse (see [Appendix B](#)) introduced into the code that can access the credit cards. Because the Trojan horse is running in the same VM as the credit card processing application, the Trojan horse only needs to exploit an OS flaw to gain access to the critical data. Most cyberattacks have used some form of Trojan horse, typically exploiting an OS flaw, that either has the effect of returning access to the attacker while leaving the CPU still in privilege mode or allows the attacker to upload and execute code as if it were part of the OS. In either case, the attacker obtains control of the CPU and, using the higher privilege mode, can proceed to access anything within the VM. Note that encryption alone does not prevent this attacker. If the data in memory is unencrypted, which is typical, then the attacker has access to all such data. Furthermore, if the attacker knows where the encryption key is stored, the attacker can freely access the key and then access any encrypted data.

More recently, Intel introduced a set of instruction set extensions, called the software guard extensions (SGX), to allow user programs to create *enclaves*, portions of code and data that are always encrypted and decrypted only on use and only with the key provided by the user code. Because the enclave is always encrypted, standard OS operations for virtual memory or I/O can access the enclave (e.g., to move a page) but cannot extract any information. For an enclave to work, all the code and all the data required must be part of the enclave. Although the topic of finer-grained protection has been around for decades, it has gotten little traction before because of the high overhead and because other solutions that are more efficient and less intrusive have been acceptable. The rise of cyberattacks and the amount of confidential information online have led to a reexamination of techniques for improving such fine-grained security. Like Intel's SGX, IBM and AMD's recent processors support on-the-fly encryption of memory.

An Example VMM: The Xen Virtual Machine

Early in the development of VMs, a number of inefficiencies became apparent. For example, a guest OS manages its virtual-to-real page mapping, but this mapping is ignored by the VMM, which performs the actual mapping to physical pages. In other words, a significant amount of wasted effort is expended just to keep the guest OS happy. To reduce such inefficiencies, VMM developers decided that it may be worthwhile to allow the guest OS to be aware that it is running on a VM. For example, a guest OS could assume a real memory as large as its virtual memory so that no memory management is required by the guest OS.

Allowing small modifications to the guest OS to simplify virtualization is referred to as *paravirtualization*, and the open source Xen VMM is a good example. The Xen VMM, which is used in Amazon's web services data centers, provides a guest OS with a virtual machine abstraction that is similar to the physical hardware, but drops many of the troublesome pieces. For example, to avoid flushing the TLB, Xen maps itself into the upper 64 MiB of the address space of each VM. Xen allows the guest OS to allocate pages, checking only to be sure the guest OS does not violate protection restrictions. To protect the guest OS from the user programs in the VM, Xen takes advantage of the four protection levels available in the 80x86. The Xen VMM runs at the highest privilege level (0), the guest OS runs at the next level (1), and the applications run at the lowest privilege level (3). Most OSes for the 80x86 keep everything at privilege levels 0 or 3.

For subsetting to work properly, Xen modifies the guest OS to not use problematic portions of the architecture. For example, the port of Linux to Xen changes about 3000 lines, or about 1% of the 80x86-specific code. These changes, however, do not affect the application binary interfaces of the guest OS.

To simplify the I/O challenge of VMs, Xen assigned privileged virtual machines to each hardware I/O device. These special VMs are called *driver domains*. (Xen calls VMs "domains.") Driver domains run the physical device drivers, although interrupts are still handled by the VMM before being sent to the appropriate driver domain. Regular VMs, called *guest domains*, run simple virtual device drivers that must communicate with the physical device drivers in the driver domains over a channel to access the physical I/O hardware. Data are sent between guest and driver domains by page remapping.

2.5

Cross-Cutting Issues: The Design of Memory Hierarchies

This section describes four topics discussed in other chapters that are fundamental to memory hierarchies.

Protection, Virtualization, and Instruction Set Architecture

Protection is a joint effort of architecture and operating systems, but architects had to modify some awkward details of existing instruction set architectures when virtual memory became popular. For example, to support virtual memory in the IBM

370, architects had to change the successful IBM 360 instruction set architecture that had been announced just 6 years before. Similar adjustments are being made today to accommodate virtual machines.

For example, the 80x86 instruction `POPF` loads the flag registers from the top of the stack in memory. One of the flags is the Interrupt Enable (IE) flag. Until recent changes to support virtualization, running the `POPF` instruction in user mode, rather than trapping it, simply changed all the flags except IE. In system mode, it does change the IE flag. Because a guest OS runs in user mode inside a VM, this was a problem, as the OS would expect to see a changed IE. Extensions of the 80x86 architecture to support virtualization eliminated this problem.

Historically, IBM mainframe hardware and VMM took three steps to improve performance of virtual machines:

1. Reduce the cost of processor virtualization.
2. Reduce interrupt overhead cost due to the virtualization.
3. Reduce interrupt cost by steering interrupts to the proper VM without invoking VMM.

IBM is still the gold standard of virtual machine technology. For example, an IBM mainframe ran thousands of Linux VMs in 2000, while Xen ran 25 VMs in 2004 (Clark et al., 2004). Recent versions of Intel and AMD chipsets have added special instructions to support devices in a VM to mask interrupts at lower levels from each VM and to steer interrupts to the appropriate VM.

Autonomous Instruction Fetch Units

Many processors with out-of-order execution and even some with simply deep pipelines decouple the instruction fetch (and sometimes initial decode), using a separate instruction fetch unit (see [Chapter 3](#)). Typically, the instruction fetch unit accesses the instruction cache to fetch an entire block before decoding it into individual instructions; such a technique is particularly useful when the instruction length varies. Because the instruction cache is accessed in blocks, it no longer makes sense to compare miss rates to processors that access the instruction cache once per instruction. In addition, the instruction fetch unit may prefetch blocks into the L1 cache; these prefetches may generate additional misses, but may actually reduce the total miss penalty incurred. Many processors also include data prefetching, which may increase the data cache miss rate, even while decreasing the total data cache miss penalty.

Speculation and Memory Access

One of the major techniques used in advanced pipelines is speculation, whereby an instruction is tentatively executed before the processor knows whether it is really needed. Such techniques rely on branch prediction, which if incorrect requires that

the speculated instructions are flushed from the pipeline. There are two separate issues in a memory system supporting speculation: protection and performance. With speculation, the processor may generate memory references, which will never be used because the instructions were the result of incorrect speculation. Those references, if executed, could generate protection exceptions. Obviously, such faults should occur only if the instruction is actually executed. In the next chapter, we will see how such “speculative exceptions” are resolved. Because a speculative processor may generate accesses to both the instruction and data caches, and subsequently not use the results of those accesses, speculation may increase the cache miss rates. As with prefetching, however, such speculation may actually lower the total cache miss penalty. The use of speculation, like the use of prefetching, makes it misleading to compare miss rates to those seen in processors without speculation, even when the ISA and cache structures are otherwise identical.

Special Instruction Caches

One of the biggest challenges in superscalar processors is to supply the instruction bandwidth. For designs that translate the instructions into micro-operations, such as most recent Arm and i7 processors, instruction bandwidth demands and branch misprediction penalties can be reduced by keeping a small cache of recently translated instructions. We explore this technique in greater depth in the next chapter.

Coherency of Cached Data

Data can be found in memory and in the cache. As long as the processor is the sole component changing or reading the data and the cache stands between the processor and memory, there is little danger in the processor seeing the old or *stale* copy. As we will see, multiple processors and I/O devices raise the opportunity for copies to be inconsistent and to read the wrong copy.

The frequency of the cache coherency problem is different for multiprocessors than for I/O. Multiple data copies are a rare event for I/O—one to be avoided whenever possible—but a program running on multiple processors will *want* to have copies of the same data in several caches. Performance of a multiprocessor program depends on the performance of the system when sharing data.

The *I/O cache coherency* question is this: where does the I/O occur in the computer—between the I/O device and the cache or between the I/O device and main memory? If input puts data into the cache and output reads data from the cache, both I/O and the processor see the same data. The difficulty in this approach is that it interferes with the processor and can cause the processor to stall for I/O. Input may also interfere with the cache by displacing some information with new data that are unlikely to be accessed soon.

The goal for the I/O system in a computer with a cache is to prevent the stale data problem while interfering as little as possible. Many systems therefore prefer that I/O occur directly to main memory, with main memory acting as an I/O buffer. If a write-through cache were used, then memory would have an up-to-date copy of the information, and there would be no stale data issue for output. (This benefit is a reason processors used write through.) However, today write through is usually found only in first-level data caches backed by an L2 cache that uses write back.

Input requires some extra work. The software solution is to guarantee that no blocks of the input buffer are in the cache. A page containing the buffer can be marked as noncachable, and the operating system can always input to such a page. Alternatively, the operating system can flush the buffer addresses from the cache before the input occurs. A hardware solution is to check the I/O addresses on input to see if they are in the cache. If there is a match of I/O addresses in the cache, the cache entries are invalidated to avoid stale data. All of these approaches can also be used for output with write-back caches.

Processor cache coherency is a critical subject in the age of multicore processors, and we will examine it in detail in [Chapter 5](#).

2.6

Putting It All Together: Memory Hierarchies in the ARM Cortex-A53 and Intel Core i7 6700

This section reveals the ARM Cortex-A53 (hereafter called the A53) and Intel Core i76700 (hereafter called i7) memory hierarchies and shows the performance of their components on a set of single-threaded benchmarks. We examine the Cortex-A53 first because it has a simpler memory system; we go into more detail for the i7, tracing out a memory reference in detail. This section presumes that readers are familiar with the organization of a two-level cache hierarchy using virtually indexed caches. The basics of such a memory system are explained in detail in [Appendix B](#), and readers who are uncertain of the organization of such a system are strongly advised to review the Opteron example in [Appendix B](#). Once they understand the organization of the Opteron, the brief explanation of the A53 system, which is similar, will be easy to follow.

The ARM Cortex-A53

The Cortex-A53 is a configurable core that supports the ARMv8A instruction set architecture, which includes both 32-bit and 64-bit modes. The Cortex-A53 is delivered as an IP (intellectual property) core. IP cores are the dominant form of technology delivery in the embedded, PMD, and related markets; billions of ARM and MIPS processors have been created from these IP cores. Note that IP cores are different from the cores in the Intel i7 or AMD Athlon multicores. An IP core (which may itself be a multicore) is designed to be incorporated with other logic (thus it is the core of a chip), including application-specific processors

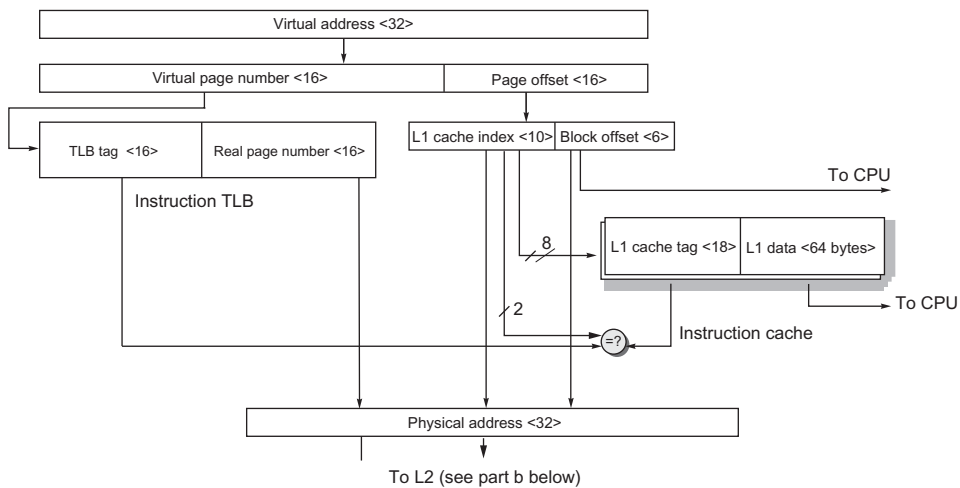

(such as an encoder or decoder for video), I/O interfaces, and memory interfaces, and then fabricated to yield a processor optimized for a particular application. For example, the Cortex-A53 IP core is used in a variety of tablets and smartphones; it is designed to be highly energy-efficient, a key criteria in battery-based PMDs. The A53 core is capable of being configured with multiple cores per chip for use in high-end PMDs; our discussion here focuses on a single core.

Generally, IP cores come in two flavors. *Hard cores* are optimized for a particular semiconductor vendor and are black boxes with external (but still on-chip) interfaces. Hard cores typically allow parametrization only of logic outside the core, such as L2 cache sizes, and the IP core cannot be modified. *Soft cores* are usually delivered in a form that uses a standard library of logic elements. A soft core can be compiled for different semiconductor vendors and can also be modified, although extensive modifications are very difficult because of the complexity of modern-day IP cores. In general, hard cores provide higher performance and smaller die area, while soft cores allow retargeting to other vendors and can be more easily modified.

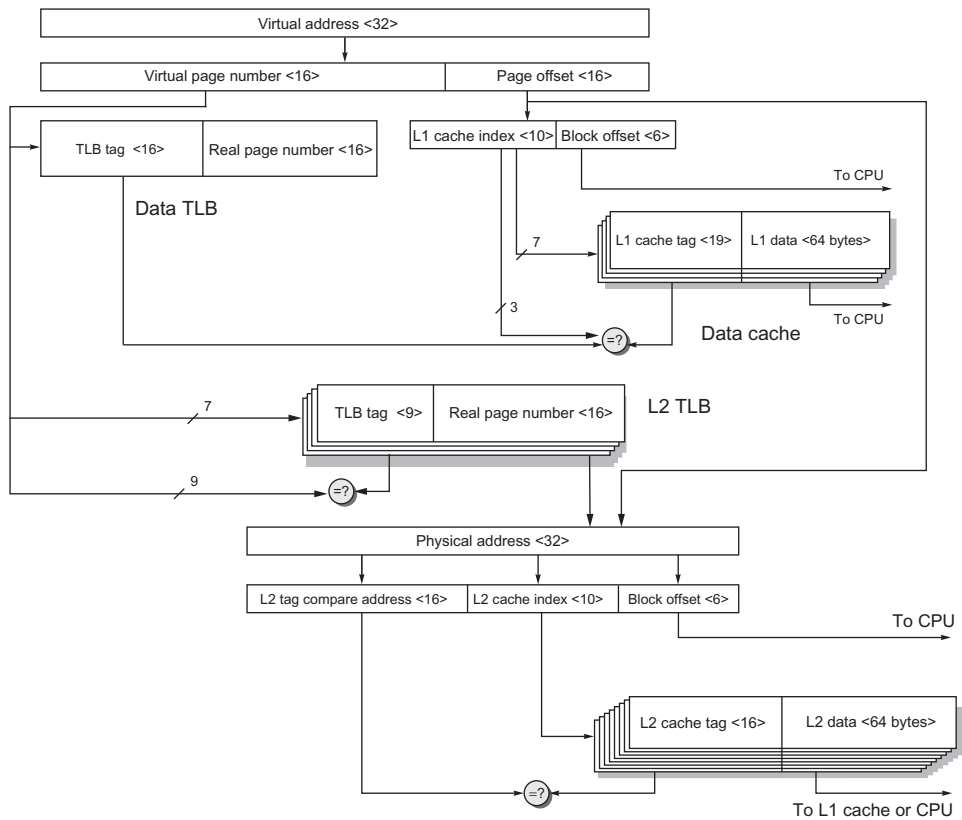

The Cortex-A53 can issue two instructions per clock at clock rates up to 1.3 GHz. It supports both a two-level TLB and a two-level cache; [Figure 2.19](#) summarizes the organization of the memory hierarchy. The critical term is returned first, and the processor can continue while the miss completes; a memory system with up to four banks can be supported. For a D-cache of 32 KiB and a page size of 4 KiB, each physical page could map to two different cache addresses; such aliases are avoided by hardware detection on a miss as in Section B.3 of [Appendix B](#). [Figure 2.20](#) shows how the 32-bit virtual address is used to index the TLB and the caches, assuming 32 KiB primary caches and a 1 MiB secondary cache with 16 KiB page size.

Structure	Size	Organization	Typical miss penalty (clock cycles)
Instruction MicroTLB	10 entries	Fully associative	2
Data MicroTLB	10 entries	Fully associative	2
L2 Unified TLB	512 entries	4-way set associative	20
L1 Instruction cache	8–64 KiB	2-way set associative; 64-byte block	13
L1 Data cache	8–64 KiB	2-way set associative; 64-byte block	13
L2 Unified cache	128 KiB to 2 MiB	16-way set associative; LRU	124

Figure 2.19 The memory hierarchy of the Cortex A53 includes multilevel TLBs and caches. A page map cache keeps track of the location of a physical page for a set of virtual pages; it reduces the L2 TLB miss penalty. The L1 caches are virtually indexed and physically tagged; both the L1 D cache and L2 use a write-back policy defaulting to allocate on write. Replacement policy is LRU approximation in all the caches. Miss penalties to L2 are higher if both a MicroTLB and L1 miss occur. The L2 to main memory bus is 64–128 bits wide, and the miss penalty is larger for the narrow bus.

(A) **The instruction access path**

(B) **The data access path**

Figure 2.20 The virtual address, physical and data blocks for the ARM Cortex-A53 caches and TLBs, assuming 32-bit addresses. The top half (A) shows the instruction access; the bottom half (B) shows the data access, including L2. The TLB (instruction or data) is fully associative each with 10 entries, using a 64 KiB page in this example. The L1 I-cache is two-way set associative, with 64-byte blocks and 32 KiB capacity; the L1 D-cache is 32 KiB, four-way set associative, and 64-byte blocks. The L2 TLB is 512 entries and four-way set associative. The L2 cache is 16-way set associative with 64-byte blocks and 128 cKiB to 2 MiB capacity; a 1 MiB L2 is shown. This figure doesn't show the valid bits and protection bits for the caches and TLB.

Performance of the Cortex-A53 Memory Hierarchy

The memory hierarchy of the Cortex-A8 was measured with 32 KiB primary caches and a 1 MiB L2 cache running the SPECInt2006 benchmarks. The instruction cache miss rates for these SPECInt2006 are very small even for just the L1: close to zero for most and under 1% for all of them. This low rate probably results from the computationally intensive nature of the SPEC CPU programs and the two-way set associative cache that eliminates most conflict misses.

Figure 2.21 shows the data cache results, which have significant L1 and L2 miss rates. The L1 rate varies by a factor of 75, from 0.5% to 37.3% with a median miss rate of 2.4%. The global L2 miss rate varies by a factor of 180, from 0.05% to 9.0% with a median of 0.3%. MCF, which is known as a cache buster, sets the upper bound and significantly affects the mean. Remember that the L2 global miss rate is significantly lower than the L2 local miss rate; for example, the median L2 stand-alone miss rate is 15.1% versus the global miss rate of 0.3%.

Using these miss penalties in Figure 2.19, Figure 2.22 shows the average penalty per data access. Although the L1 miss rates are about seven times higher than the L2 miss rate, the L2 penalty is 9.5 times as high, leading to L2 misses slightly dominating for the benchmarks that stress the memory system. In the next chapter, we will examine the impact of the cache misses on overall CPI.

Figure 2.21 The data miss rate for ARM with a 32 KiB L1 and the global data miss rate for a 1 MiB L2 using the SPECInt2006 benchmarks are significantly affected by the applications. Applications with larger memory footprints tend to have higher miss rates in both L1 and L2. Note that the L2 rate is the global miss rate that is counting all references, including those that hit in L1. MCF is known as a cache buster.

Figure 2.22 The average memory access penalty per data memory reference coming from L1 and L2 is shown for the A53 processor when running SPECint2006. Although the miss rates for L1 are significantly higher, the L2 miss penalty, which is more than five times higher, means that the L2 misses can contribute significantly.

The Intel Core i7 6700

The i7 supports the x86-64 instruction set architecture, a 64-bit extension of the 80x86 architecture. The i7 is an out-of-order execution processor that includes four cores. In this chapter, we focus on the memory system design and performance from the viewpoint of a single core. The system performance of multiprocessor designs, including the i7 multicore, is examined in detail in [Chapter 5](#).

Each core in an i7 can execute up to four 80x86 instructions per clock cycle, using a multiple issue, dynamically scheduled, 16-stage pipeline, which we describe in detail in [Chapter 3](#). The i7 can also support up to two simultaneous threads per processor, using a technique called simultaneous multithreading, described in [Chapter 4](#). In 2017 the fastest i7 had a clock rate of 4.0 GHz (in Turbo Boost mode), which yielded a peak instruction execution rate of 16 billion instructions per second, or 64 billion instructions per second for the four-core design. Of course, there is a big gap between peak and sustained performance, as we will see over the next few chapters.

The i7 can support up to three memory channels, each consisting of a separate set of DIMMs, and each of which can transfer in parallel. Using DDR3-1066 (DIMM PC8500), the i7 has a peak memory bandwidth of just over 25 GB/s.

i7 uses 48-bit virtual addresses and 36-bit physical addresses, yielding a maximum physical memory of 36 GiB. Memory management is handled with a two-level TLB (see [Appendix B](#), Section B.4), summarized in [Figure 2.23](#).

[Figure 2.24](#) summarizes the i7's three-level cache hierarchy. The first-level caches are virtually indexed and physically tagged (see [Appendix B](#), Section B.3), while the L2 and L3 caches are physically indexed. Some versions of the i7 6700 will support a fourth-level cache using HBM packaging.

[Figure 2.25](#) is labeled with the steps of an access to the memory hierarchy. First, the PC is sent to the instruction cache. The instruction cache index is

$$2^{\text{Index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}} = \frac{32\text{K}}{64 \times 8} = 64 = 2^6$$

Characteristic	Instruction TLB	Data DLB	Second-level TLB
Entries	128	64	1536
Associativity	8-way	4-way	12-way
Replacement	Pseudo-LRU	Pseudo-LRU	Pseudo-LRU
Access latency	1 cycle	1 cycle	8 cycles
Miss	9 cycles	9 cycles	Hundreds of cycles to access page table

Figure 2.23 Characteristics of the i7's TLB structure, which has separate first-level instruction and data TLBs, both backed by a joint second-level TLB. The first-level TLBs support the standard 4 KiB page size, as well as having a limited number of entries of large 2–4 MiB pages; only 4 KiB pages are supported in the second-level TLB. The i7 has the ability to handle two L2 TLB misses in parallel. See Section L.3 of online Appendix L for more discussion of multilevel TLBs and support for multiple page sizes.

Characteristic	L1	L2	L3
Size	32 KiB I/32 KiB D	256 KiB	2 MiB per core
Associativity	both 8-way	4-way	16-way
Access latency	4 cycles, pipelined	12 cycles	44 cycles
Replacement scheme	Pseudo-LRU	Pseudo-LRU	Pseudo-LRU but with an ordered selection algorithm

Figure 2.24 Characteristics of the three-level cache hierarchy in the i7. All three caches use write back and a block size of 64 bytes. The L1 and L2 caches are separate for each core, whereas the L3 cache is shared among the cores on a chip and is a total of 2 MiB per core. All three caches are nonblocking and allow multiple outstanding writes. A merging write buffer is used for the L1 cache, which holds data in the event that the line is not present in L1 when it is written. (That is, an L1 write miss does not cause the line to be allocated.) L3 is inclusive of L1 and L2; we explore this property in further detail when we explain multiprocessor caches. Replacement is by a variant on pseudo-LRU; in the case of L3, the block replaced is always the lowest numbered way whose access bit is off. This is not quite random but is easy to compute.

Figure 2.25 The Intel i7 memory hierarchy and the steps in both instruction and data access. We show only reads. Writes are similar, except that misses are handled by simply placing the data in a write buffer, because the L1 cache is not write-allocated.

or 6 bits. The page frame of the instruction's address ($36 = 48 - 12$ bits) is sent to the instruction TLB (step 1). At the same time, the 12-bit page offset from the virtual address is sent to the instruction cache (step 2). Notice that for the eight-way associative instruction cache, 12 bits are needed for the cache address: 6 bits to index the cache plus 6 bits of block offset for the 64-byte block, so no aliases are possible. The previous versions of the i7 used a four-way set associative I-cache, meaning that a block corresponding to a virtual address could actually be in two different places in the cache, because the corresponding physical address could have either a 0 or 1 in this location. For instructions this did not pose a problem because even if an instruction appeared in the cache in two different locations, the two versions must be the same. If such duplication, or aliasing, of data is allowed, the cache must be checked when the page map is changed, which is an infrequent event. Note that a very simple use of page coloring (see [Appendix B](#), Section B.3) can eliminate the possibility of these aliases. If even-address virtual pages are mapped to even-address physical pages (and the same for odd pages), then these aliases can never occur because the low-order bit in the virtual and physical page number will be identical.

The instruction TLB is accessed to find a match between the address and a valid page table entry (PTE) (steps 3 and 4). In addition to translating the address, the TLB checks to see if the PTE demands that this access result in an exception because of an access violation.

An instruction TLB miss first goes to the L2 TLB, which contains 1536 PTEs of 4 KiB page sizes and is 12-way set associative. It takes 8 clock cycles to load the L1 TLB from the L2 TLB, which leads to the 9-cycle miss penalty including the initial clock cycle to access the L1 TLB. If the L2 TLB misses, a hardware algorithm is used to walk the page table and update the TLB entry. Sections L.5 and L.6 of online Appendix L describe page table walkers and page structure caches. In the worst case, the page is not in memory, and the operating system gets the page from secondary storage. Because millions of instructions could execute during a page fault, the operating system will swap in another process if one is waiting to run. Otherwise, if there is no TLB exception, the instruction cache access continues.

The index field of the address is sent to all eight banks of the instruction cache (step 5). The instruction cache tag is 36 bits – 6 bits (index) – 6 bits (block offset), or 24 bits. The four tags and valid bits are compared to the physical page frame from the instruction TLB (step 6). Because the i7 expects 16 bytes each instruction fetch, an additional 2 bits are used from the 6-bit block offset to select the appropriate 16 bytes. Therefore 6 + 2 or 8 bits are used to send 16 bytes of instructions to the processor. The L1 cache is pipelined, and the latency of a hit is 4 clock cycles (step 7). A miss goes to the second-level cache.

As mentioned earlier, the instruction cache is virtually addressed and physically tagged. Because the second-level caches are physically addressed, the physical page address from the TLB is composed with the page offset to make an address to access the L2 cache. The L2 index is

$$2^{\text{Index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}} = \frac{256\text{K}}{64 \times 4} = 1024 = 2^{10}$$

so the 30-bit block address (36-bit physical address – 6-bit block offset) is divided into a 20-bit tag and a 10-bit index (step 8). Once again, the index and tag are sent to the four banks of the unified L2 cache (step 9), which are compared in parallel. If one matches and is valid (step 10), it returns the block in sequential order after the initial 12-cycle latency at a rate of 8 bytes per clock cycle.

If the L2 cache misses, the L3 cache is accessed. For a four-core i7, which has an 8 MiB L3, the index size is

$$2^{\text{Index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}} = \frac{8\text{M}}{64 \times 16} = 8192 = 2^{13}$$

The 13-bit index (step 11) is sent to all 16 banks of the L3 (step 12). The L3 tag, which is $36 - (13 + 6) = 17$ bits, is compared against the physical address from the TLB (step 13). If a hit occurs, the block is returned after an initial latency of 42 clock cycles, at a rate of 16 bytes per clock and placed into both L1 and L3. If L3 misses, a memory access is initiated.

If the instruction is not found in the L3 cache, the on-chip memory controller must get the block from main memory. The i7 has three 64-bit memory channels that can act as one 192-bit channel, because there is only one memory controller and the same address is sent on both channels (step 14). Wide transfers happen when both channels have identical DIMMs. Each channel supports up to four DDR DIMMs (step 15). When the data return they are placed into L3 and L1 (step 16) because L3 is inclusive.

The total latency of the instruction miss that is serviced by main memory is approximately 42 processor cycles to determine that an L3 miss has occurred, plus the DRAM latency for the critical instructions. For a single-bank DDR4-2400 SDRAM and 4.0 GHz CPU, the DRAM latency is about 40 ns or 160 clock cycles to the first 16 bytes, leading to a total miss penalty of about 200 clock cycles. The memory controller fills the remainder of the 64-byte cache block at a rate of 16 bytes per I/O bus clock cycle, which takes another 5 ns or 20 clock cycles.

Because the second-level cache is a write-back cache, any miss can lead to an old block being written back to memory. The i7 has a 10-entry merging write buffer that writes back dirty cache lines when the next level in the cache is unused for a read. The write buffer is checked on a miss to see if the cache line exists in the buffer; if so, the miss is filled from the buffer. A similar buffer is used between the L1 and L2 caches. If this initial instruction is a load, the data address is sent to the data cache and data TLBs, acting very much like an instruction cache access.

Suppose the instruction is a store instead of a load. When the store issues, it does a data cache lookup just like a load. A miss causes the block to be placed in a write buffer because the L1 cache does not allocate the block on a write miss. On a hit, the store does not update the L1 (or L2) cache until later, after it is known to be nonspeculative. During this time, the store resides in a load-store queue, part of the out-of-order control mechanism of the processor.

The I7 also supports prefetching for L1 and L2 from the next level in the hierarchy. In most cases, the prefetched line is simply the next block in the cache. By prefetching only for L1 and L2, high-cost unnecessary fetches to memory are avoided.

Performance of the i7 memory system

We evaluate the performance of the i7 cache structure using the SPECint2006 benchmarks. The data in this section were collected by Professor Lu Peng and PhD student Qun Liu, both of Louisiana State University. Their analysis is based on earlier work (see [Prakash and Peng, 2008](#)).

The complexity of the i7 pipeline, with its use of an autonomous instruction fetch unit, speculation, and both instruction and data prefetch, makes it hard to compare cache performance against simpler processors. As mentioned on page 110, processors that use prefetch can generate cache accesses independent of the memory accesses performed by the program. A cache access that is generated because of an actual instruction access or data access is sometimes called a *demand access* to distinguish it from a *prefetch access*. Demand accesses can come from both speculative instruction fetches and speculative data accesses, some of which are subsequently canceled (see [Chapter 3](#) for a detailed description of speculation and instruction graduation). A speculative processor generates at least as many misses as an in-order nonspeculative processor, and typically more. In addition to demand misses, there are prefetch misses for both instructions and data.

The i7's instruction fetch unit attempts to fetch 16 bytes every cycle, which complicates comparing instruction cache miss rates because multiple instructions are fetched every cycle (roughly 4.5 on average). In fact, the entire 64-byte cache line is read and subsequent 16-byte fetches do not require additional accesses. Thus misses are tracked only on the basis of 64-byte blocks. The 32 KiB, eight-way set associative instruction cache leads to a very low instruction miss rate for the SPECint2006 programs. If, for simplicity, we measure the miss rate of SPECint2006 as the number of misses for a 64-byte block divided by the number of instructions that complete, the miss rates are all under 1% except for one benchmark (XALANCBMK), which has a 2.9% miss rate. Because a 64-byte block typically contains 16–20 instructions, the effective miss rate per instruction is much lower, depending on the degree of spatial locality in the instruction stream.

The frequency at which the instruction fetch unit is stalled waiting for the I-cache misses is similarly small (as a percentage of total cycles) increasing to 2% for two benchmarks and 12% for XALANCBMK, which has the highest I-cache miss rate. In the next chapter, we will see how stalls in the IFU contribute to overall reductions in pipeline throughput in the i7.

The L1 data cache is more interesting and even trickier to evaluate because in addition to the effects of prefetching and speculation, the L1 data cache is not write-allocated, and writes to cache blocks that are not present are not treated as misses. For this reason, we focus only on memory reads. The performance monitor measurements in the i7 separate out prefetch accesses from demand accesses, but only keep demand accesses for those instructions that graduate. The effect of speculative instructions that do not graduate is not negligible, although pipeline effects probably dominate secondary cache effects caused by speculation; we will return to the issue in the next chapter.

Figure 2.26 The L1 data cache miss rate for the SPECint2006 benchmarks is shown in two ways relative to the demand L1 reads: one including both demand and prefetch accesses and one including only demand accesses. The i7 separates out L1 misses for a block not present in the cache and L1 misses for a block already outstanding that is being prefetched from L2; we treat the latter group as hits because they would hit in a blocking cache. These data, like the rest in this section, were collected by Professor Lu Peng and PhD student Qun Liu, both of Louisiana State University, based on earlier studies of the Intel Core Duo and other processors (see Peng et al., 2008).

To address these issues, while keeping the amount of data reasonable, [Figure 2.26](#) shows the L1 data cache misses in two ways:

1. The L1 miss rate relative to demand references given by the L1 miss rate including prefetches and speculative loads/L1 demand read references for those instructions that graduate.

2. The demand miss rate given by $L1 \text{ demand misses} / L1 \text{ demand read references}$, both measurements only for instructions that graduate.

On average, the miss rate including prefetches is 2.8 times as high as the demand-only miss rate. Comparing this data to that from the earlier i7 920, which had the same size L1, we see that the miss rate including prefetches is higher on the newer i7, but the number of demand misses, which are more likely to cause a stall, are usually fewer.

To understand the effectiveness of the aggressive prefetch mechanisms in the i7, let's look at some measurements of prefetching. Figure 2.27 shows both the fraction of L2 requests that are prefetches versus demand requests and the prefetch miss rate. The data are probably astonishing at first glance: there are roughly 1.5 times as many prefetches as there are L2 demand requests, which come directly from L1 misses. Furthermore, the prefetch miss rate is amazingly high, with an average miss rate of 58%. Although the prefetch ratio varies considerably, the prefetch miss rate is always significant. At first glance, you might conclude that the designers made a mistake: they are prefetching too much, and the miss rate is too high. Notice, however, that the benchmarks with the higher prefetch ratios (ASTAR, BZIP2, HMMER, LIBQUANTUM, and OMNETPP) also show the greatest gap between the prefetch miss rate and the demand miss rate, more than a factor of 2 in each case. The aggressive prefetching is trading prefetch misses, which occur earlier, for demand misses, which occur later; and as a result, a pipeline stall is less likely to occur due to the prefetching.

Similarly, consider the high prefetch miss rate. Suppose that the majority of the prefetches are actually useful (this is hard to measure because it involves tracking individual cache blocks), then a prefetch miss indicates a likely L2 cache miss in the future. Uncovering and handling the miss earlier via the prefetch is likely to reduce the stall cycles. Performance analysis of speculative superscalars, like the i7, has shown that cache misses tend to be the primary cause of pipeline stalls, because it is hard to keep the processor going, especially for longer running L2 and L3 misses. The Intel designers could not easily increase the size of the caches without incurring both energy and cycle time impacts; thus the use of aggressive prefetching to try to lower effective cache miss penalties is an interesting alternative approach.

With the combination of the L1 demand misses and prefetches going to L2, roughly 17% of the loads generate an L2 request. Analyzing L2 performance requires including the effects of writes (because L2 is write-allocated), as well as the prefetch hit rate and the demand hit rate. Figure 2.28 shows the miss rates of the L2 caches for demand and prefetch accesses, both versus the number of L1 references (reads and writes). As with L1, prefetches are a significant contributor, generating 75% of the L2 misses. Comparing the L2 demand miss rate with that of earlier i7 implementations (again with the same L2 size) shows that the i7 6700 has a lower L2 demand miss rate by an approximate factor of 2, which may well justify the higher prefetch miss rate.

Figure 2.27 The fraction of L2 requests that are prefetches is shown via the columns and the left axis. The right axis and the line shows the prefetch hit rate. These data, like the rest in this section, were collected by Professor Lu Peng and PhD student Qun Liu, both of Louisiana State University, based on earlier studies of the Intel Core Duo and other processors (see Peng et al., 2008).

Because the cost for a miss to memory is over 100 cycles and the average data miss rate in L2 combining both prefetch and demand misses is over 7%, L3 is obviously critical. Without L3 and assuming that about one-third of the instructions are loads or stores, L2 cache misses could add over two cycles per instruction to the CPI! Obviously, prefetching past L2 would make no sense without an L3.

In comparison, the average L3 data miss rate of 0.5% is still significant but less than one-third of the L2 demand miss rate and 10 times less than the L1 demand miss rate. Only in two benchmarks (OMNETPP and MCF) is the L3 miss rate

Figure 2.28 The L2 demand miss rate and prefetch miss rate, both shown relative to all the references to L1, which also includes prefetches, speculative loads that do not complete, and program-generated loads and stores (demand references). These data, like the rest in this section, were collected by Professor Lu Peng and PhD student Qun Liu, both of Louisiana State University.

above 0.5%; in those two cases, the miss rate of about 2.3% likely dominates all other performance losses. In the next chapter, we will examine the relationship between the i7 CPI and cache misses, as well as other pipeline effects.

2.7

Fallacies and Pitfalls

As the most naturally quantitative of the computer architecture disciplines, memory hierarchy would seem to be less vulnerable to fallacies and pitfalls. Yet we were limited here not by lack of warnings, but by lack of space!

Fallacy *Predicting cache performance of one program from another.*

Figure 2.29 shows the instruction miss rates and data miss rates for three programs from the SPEC2000 benchmark suite as cache size varies. Depending on the

Figure 2.29 Instruction and data misses per 1000 instructions as cache size varies from 4 KiB to 4096 KiB. Instruction misses for gcc are 30,000–40,000 times larger than for lucas, and, conversely, data misses for lucas are 2–60 times larger than for gcc. The programs gap, gcc, and lucas are from the SPEC2000 benchmark suite.

program, the data misses per thousand instructions for a 4096 KiB cache are 9, 2, or 90, and the instruction misses per thousand instructions for a 4 KiB cache are 55, 19, or 0.0004. Commercial programs such as databases will have significant miss rates even in large second-level caches, which is generally not the case for the SPECCPU programs. Clearly, generalizing cache performance from one program to another is unwise. As [Figure 2.24](#) reminds us, there is a great deal of variation, and even predictions about the relative miss rates of integer and floating-point-intensive programs can be wrong, as *mcf* and *sphinx3* remind us!

Pitfall *Simulating enough instructions to get accurate performance measures of the memory hierarchy.*

There are really three pitfalls here. One is trying to predict performance of a large cache using a small trace. Another is that a program’s locality behavior is not constant over the run of the entire program. The third is that a program’s locality behavior may vary depending on the input.

[Figure 2.30](#) shows the cumulative average instruction misses per thousand instructions for five inputs to a single SPEC2000 program. For these inputs, the average memory rate for the first 1.9 billion instructions is very different from the average miss rate for the rest of the execution.

Pitfall *Not delivering high memory bandwidth in a cache-based system.*

Caches help with average cache memory latency but may not deliver high memory bandwidth to an application that must go to main memory. The architect must design a high bandwidth memory behind the cache for such applications. We will revisit this pitfall in [Chapters 4 and 5](#).

Figure 2.30 Instruction misses per 1000 references for five inputs to the perl benchmark in SPEC2000. There is little variation in misses and little difference between the five inputs for the first 1.9 billion instructions. Running to completion shows how misses vary over the life of the program and how they depend on the input. The top graph shows the running average misses for the first 1.9 billion instructions, which starts at about 2.5 and ends at about 4.7 misses per 1000 references for all five inputs. The bottom graph shows the running average misses to run to completion, which takes 16–41 billion instructions depending on the input. After the first 1.9 billion instructions, the misses per 1000 references vary from 2.4 to 7.9 depending on the input. The simulations were for the Alpha processor using separate L1 caches for instructions and data, each being two-way 64 KiB with LRU, and a unified 1 MiB direct-mapped L2 cache.

Pitfall *Implementing a virtual machine monitor on an instruction set architecture that wasn't designed to be virtualizable.*

Many architects in the 1970s and 1980s weren't careful to make sure that all instructions reading or writing information related to hardware resource information were privileged. This *laissez faire* attitude causes problems for VMMs for all of these architectures, including the 80x86, which we use here as an example.

Figure 2.31 describes the 18 instructions that cause problems for paravirtualization (Robin and Irvine, 2000). The two broad classes are instructions that

- read control registers in user mode that reveal that the guest operating system is running in a virtual machine (such as POPF mentioned earlier) and
- check protection as required by the segmented architecture but assume that the operating system is running at the highest privilege level.

Virtual memory is also challenging. Because the 80x86 TLBs do not support process ID tags, as do most RISC architectures, it is more expensive for the VMM and guest OSes to share the TLB; each address space change typically requires a TLB flush.

Problem category	Problem 80x86 instructions
Access sensitive registers without trapping when running in user mode	Store global descriptor table register (SGDT) Store local descriptor table register (SLDT) Store interrupt descriptor table register (SIDT) Store machine status word (SMSW) Push flags (PUSHF, PUSHFD) Pop flags (POPF, POPFD)
When accessing virtual memory mechanisms in user mode, instructions fail the 80x86 protection checks	Load access rights from segment descriptor (LAR) Load segment limit from segment descriptor (LSL) Verify if segment descriptor is readable (VERR) Verify if segment descriptor is writable (VERW) Pop to segment register (POP CS, POP SS, ...) Push segment register (PUSH CS, PUSH SS, ...) Far call to different privilege level (CALL) Far return to different privilege level (RET) Far jump to different privilege level (JMP) Software interrupt (INT) Store segment selector register (STR) Move to/from segment registers (MOVE)

Figure 2.31 Summary of 18 80x86 instructions that cause problems for virtualization (Robin and Irvine, 2000). The first five instructions of the top group allow a program in user mode to read a control register, such as a descriptor table register without causing a trap. The pop flags instruction modifies a control register with sensitive information but fails silently when in user mode. The protection checking of the segmented architecture of the 80x86 is the downfall of the bottom group because each of these instructions checks the privilege level implicitly as part of instruction execution when reading a control register. The checking assumes that the OS must be at the highest privilege level, which is not the case for guest VMs. Only the MOVE to segment register tries to modify control state, and protection checking foils it as well.

Virtualizing I/O is also a challenge for the 80x86, in part because it supports memory-mapped I/O and has separate I/O instructions, but more importantly because there are a very large number and variety of types of devices and device drivers of PCs for the VMM to handle. Third-party vendors supply their own drivers, and they may not properly virtualize. One solution for conventional VM implementations is to load real device drivers directly into the VMM.

To simplify implementations of VMMs on the 80x86, both AMD and Intel have proposed extensions to the architecture. Intel's VT-x provides a new execution mode for running VMs, a architected definition of the VM state, instructions to swap VMs rapidly, and a large set of parameters to select the circumstances where a VMM must be invoked. Altogether, VT-x adds 11 new instructions for the 80x86. AMD's Secure Virtual Machine (SVM) provides similar functionality.

After turning on the mode that enables VT-x support (via the new `VMXON` instruction), VT-x offers four privilege levels for the guest OS that are lower in priority than the original four (and fix issues like the problem with the `POPF` instruction mentioned earlier). VT-x captures all the states of a virtual machine in the Virtual Machine Control State (VMCS) and then provides atomic instructions to save and restore a VMCS. In addition to critical state, the VMCS includes configuration information to determine when to invoke the VMM and then specifically what caused the VMM to be invoked. To reduce the number of times the VMM must be invoked, this mode adds shadow versions of some sensitive registers and adds masks that check to see whether critical bits of a sensitive register will be changed before trapping. To reduce the cost of virtualizing virtual memory, AMD's SVM adds an additional level of indirection, called *nested page tables*, which makes shadow page tables unnecessary (see Section L.7 of Appendix L).

2.8

Concluding Remarks: Looking Ahead

Over the past thirty years there have been several predictions of the eminent [sic] cessation of the rate of improvement in computer performance. Every such prediction was wrong. They were wrong because they hinged on unstated assumptions that were overturned by subsequent events. So, for example, the failure to foresee the move from discrete components to integrated circuits led to a prediction that the speed of light would limit computer speeds to several orders of magnitude slower than they are now. Our prediction of the memory wall is probably wrong too but it suggests that we have to start thinking "out of the box."

Wm. A. Wulf and Sally A. McKee,

Hitting the Memory Wall: Implications of the Obvious,

Department of Computer Science, University of Virginia (December 1994).

This paper introduced the term *memory wall*.

The possibility of using a memory hierarchy dates back to the earliest days of general-purpose digital computers in the late 1940s and early 1950s. Virtual memory was introduced in research computers in the early 1960s and into IBM mainframes in the 1970s. Caches appeared around the same time. The basic concepts

have been expanded and enhanced over time to help close the access time gap between main memory and processors, but the basic concepts remain.

One trend that is causing a significant change in the design of memory hierarchies is a continued slowdown in both density and access time of DRAMs. In the past 15 years, both these trends have been observed and have been even more obvious over the past 5 years. While some increases in DRAM bandwidth have been achieved, decreases in access time have come much more slowly and almost vanished between DDR4 and DDR3. The end of Dennard scaling as well as a slowdown in Moore's Law both contributed to this situation. The trenched capacitor design used in DRAMs is also limiting its ability to scale. It may well be the case that packaging technologies such as stacked memory will be the dominant source of improvements in DRAM access bandwidth and latency.

Independently of improvements in DRAM, Flash memory has been playing a much larger role. In PMDs, Flash has dominated for 15 years and became the standard for laptops almost 10 years ago. In the past few years, many desktops have shipped with Flash as the primary secondary storage. Flash's potential advantage over DRAMs, specifically the absence of a per-bit transistor to control writing, is also its Achilles heel. Flash must use bulk erase-rewrite cycles that are considerably slower. As a result, although Flash has become the fastest growing form of secondary storage, SDRAMs still dominate for main memory.

Although phase-change materials as a basis for memory have been around for a while, they have never been serious competitors either for magnetic disks or for Flash. The recent announcement by Intel and Micron of the cross-point technology may change this. The technology appears to have several advantages over Flash, including the elimination of the slow erase-to-write cycle and greater longevity in terms. It could be that this technology will finally be the technology that replaces the electro-mechanical disks that have dominated bulk storage for more than 50 years!

For some years, a variety of predictions have been made about the coming memory wall (see previously cited quote and paper), which would lead to serious limits on processor performance. Fortunately, the extension of caches to multiple levels (from 2 to 4), more sophisticated refill and prefetch schemes, greater compiler and programmer awareness of the importance of locality, and tremendous improvements in DRAM bandwidth (a factor of over 150 times since the mid-1990s) have helped keep the memory wall at bay. In recent years, the combination of access time constraints on the size of L1 (which is limited by the clock cycle) and energy-related limitations on the size of L2 and L3 have raised new challenges. The evolution of the i7 processor class over 6–7 years illustrates this: the caches are the same size in the i7 6700 as they were in the first generation i7 processors! The more aggressive use of prefetching is an attempt to overcome the inability to increase L2 and L3. Off-chip L4 caches are likely to become more important because they are less energy-constrained than on-chip caches.

In addition to schemes relying on multilevel caches, the introduction of out-of-order pipelines with multiple outstanding misses has allowed available instruction-level parallelism to hide the memory latency remaining in a cache-based system. The introduction of multithreading and more thread-level parallelism takes this a step further by providing more parallelism and thus more latency-hiding

opportunities. It is likely that the use of instruction- and thread-level parallelism will be a more important tool in hiding whatever memory delays are encountered in modern multilevel cache systems.

One idea that periodically arises is the use of programmer-controlled scratchpad or other high-speed visible memories, which we will see are used in GPUs. Such ideas have never made the mainstream in general-purpose processors for several reasons: First, they break the memory model by introducing address spaces with different behavior. Second, unlike compiler-based or programmer-based cache optimizations (such as prefetching), memory transformations with scratchpads must completely handle the remapping from main memory address space to the scratchpad address space. This makes such transformations more difficult and limited in applicability. In GPUs (see [Chapter 4](#)), where local scratchpad memories are heavily used, the burden for managing them currently falls on the programmer. For domain-specific software systems that can use such memories, the performance gains are very significant. It is likely that HBM technologies will thus be used for caching in large, general-purpose computers and quite possibly as the main working memories in graphics and similar systems. As domain-specific architectures become more important in overcoming the limitations arising from the end of Dennard's Law and the slowdown in Moore's Law (see [Chapter 7](#)), scratchpad memories and vector-like register sets are likely to see more use.

The implications of the end of Dennard's Law affect both DRAM and processor technology. Thus, rather than a widening gulf between processors and main memory, we are likely to see a slowdown in both technologies, leading to slower overall growth rates in performance. New innovations in computer architecture and in related software that together increase performance and efficiency will be key to continuing the performance improvements seen over the past 50 years.

2.9

Historical Perspectives and References

In Section M.3 (available online) we examine the history of caches, virtual memory, and virtual machines. IBM plays a prominent role in the history of all three. References for further reading are included.

Case Studies and Exercises by Norman P. Jouppi, Rajeev Balasubramonian, Naveen Muralimanohar, and Sheng Li

Case Study 1: Optimizing Cache Performance via Advanced Techniques

Concepts illustrated by this case study

- Nonblocking Caches
- Compiler Optimizations for Caches
- Software and Hardware Prefetching
- Calculating Impact of Cache Performance on More Complex Processors

The transpose of a matrix interchanges its rows and columns; this concept is illustrated here:

$$\begin{bmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ A_{21} & A_{22} & A_{23} & A_{24} \\ A_{31} & A_{32} & A_{33} & A_{34} \\ A_{41} & A_{42} & A_{43} & A_{44} \end{bmatrix} \Rightarrow \begin{bmatrix} A_{11} & A_{21} & A_{31} & A_{41} \\ A_{12} & A_{22} & A_{32} & A_{42} \\ A_{13} & A_{23} & A_{33} & A_{43} \\ A_{14} & A_{24} & A_{34} & A_{44} \end{bmatrix}$$

Here is a simple C loop to show the transpose:

```
for (i = 0; i < 3; i++) {
    for (j = 0; j < 3; j++) {
        output[j][i] = input[i][j];
    }
}
```

Assume that both the input and output matrices are stored in the row major order (*row major order* means that the row index changes fastest). Assume that you are executing a 256-256 double-precision transpose on a processor with a 16 KB fully associative (don't worry about cache conflicts) least recently used (LRU) replacement L1 data cache with 64-byte blocks. Assume that the L1 cache misses or pre-fetches require 16 cycles and always hit in the L2 cache, and that the L2 cache can process a request every 2 processor cycles. Assume that each iteration of the preceding inner loop requires 4 cycles if the data are present in the L1 cache. Assume that the cache has a write-allocate fetch-on-write policy for write misses. Unrealistically, assume that writing back dirty cache blocks requires 0 cycles.

- 2.1 [10/15/15/12/20] <2.3> For the preceding simple implementation, this execution order would be nonideal for the input matrix; however, applying a loop interchange optimization would create a nonideal order for the output matrix. Because loop interchange is not sufficient to improve its performance, it must be blocked instead.
- [10] <2.3> What should be the minimum size of the cache to take advantage of blocked execution?
 - [15] <2.3> How do the relative number of misses in the blocked and unblocked versions compare in the preceding minimum-sized cache?
 - [15] <2.3> Write code to perform a transpose with a block size parameter B that uses $B \cdot B$ blocks.
 - [12] <2.3> What is the minimum associativity required of the L1 cache for consistent performance independent of both arrays' position in memory?
 - [20] <2.3> Try out blocked and nonblocked 256-256 matrix transpositions on a computer. How closely do the results match your expectations based on what you know about the computer's memory system? Explain any discrepancies if possible.

- 2.2 [10] <2.3> Assume you are designing a hardware prefetcher for the preceding *unblocked* matrix transposition code. The simplest type of hardware prefetcher only prefetches sequential cache blocks after a miss. More complicated “nonunit stride” hardware prefetchers can analyze a miss reference stream and detect and prefetch nonunit strides. In contrast, software prefetching can determine nonunit strides as easily as it can determine unit strides. Assume prefetches write directly into the cache and that there is no “pollution” (overwriting data that must be used before the data that are prefetched). For best performance given a nonunit stride prefetcher, in the steady state of the inner loop, how many prefetches must be outstanding at a given time?
- 2.3 [15/20] <2.3> With software prefetching, it is important to be careful to have the prefetches occur in time for use but also to minimize the number of outstanding prefetches to live within the capabilities of the microarchitecture and minimize cache pollution. This is complicated by the fact that different processors have different capabilities and limitations.
- [15] <2.3> Create a blocked version of the matrix transpose with software prefetching.
 - [20] <2.3> Estimate and compare the performance of the blocked and unblocked transpose codes both with and without software prefetching.

Case Study 2: Putting It All Together: Highly Parallel Memory Systems

Concept illustrated by this case study

■ Cross-Cutting Issues: The Design of Memory Hierarchies

The program in [Figure 2.32](#) can be used to evaluate the behavior of a memory system. The key is having accurate timing and then having the program stride through memory to invoke different levels of the hierarchy. [Figure 2.32](#) shows the code in C. The first part is a procedure that uses a standard utility to get an accurate measure of the user CPU time; this procedure may have to be changed to work on some systems. The second part is a nested loop to read and write memory at different strides and cache sizes. To get accurate cache timing, this code is repeated many times. The third part times the nested loop overhead only so that it can be subtracted from overall measured times to see how long the accesses were. The results are output in .csv file format to facilitate importing into spreadsheets. You may need to change `CACHE_MAX` depending on the question you are answering and the size of memory on the system you are measuring. Running the program in single-user mode or at least without other active applications will give more consistent results. The code in [Figure 2.32](#) was derived from a program written by Andrea Duseau at the University of California-Berkeley and was based on a detailed description found in [Saavedra-Barrera \(1992\)](#). It has been modified to fix a number of issues with more modern machines and to run under Microsoft

```

#include "stdafx.h"
#include <stdio.h>
#include <time.h>
#define ARRAY_MIN (1024) /* 1/4 smallest cache */
#define ARRAY_MAX (4096*4096) /* 1/4 largest cache */
int x[ARRAY_MAX]; /* array going to stride through */

double get_seconds() { /* routine to read time in seconds */
    __time64_t ltime;
    _time64( &ltime );
    return (double) ltime;
}

int label(int i) { /* generate text labels */
    if (i<1e3) printf("%ldB",i);
    else if (i<1e6) printf("%ldK",i/1024);
    else if (i<1e9) printf("%ldM",i/1048576);
    else printf("%ldG",i/1073741824);
    return 0;
}

int _tmain(int argc, _TCHAR* argv[]) {
    int register nextstep, i, index, stride;
    int csize;
    double steps, tsteps;
    double loadtime, lastsec, sec0, sec1, sec; /* timing variables */

    /* Initialize output */
    printf(" ");
    for (stride=1; stride <= ARRAY_MAX/2; stride=stride*2)
        label(stride*sizeof(int));
    printf("\n");

    /* Main loop for each configuration */
    for (csize=ARRAY_MIN; csize <= ARRAY_MAX; csize=csize*2) {
        label(csize*sizeof(int)); /* print cache size this loop */
        for (stride=1; stride <= csize/2; stride=stride*2) {

            /* Lay out path of memory references in array */
            for (index=0; index < csize; index=index+stride)
                x[index] = index + stride; /* pointer to next */
            x[index-stride] = 0; /* loop back to beginning */

            /* Wait for timer to roll over */
            lastsec = get_seconds();
            sec0 = get_seconds(); while (sec0 == lastsec);

            /* Walk through path in array for twenty seconds */
            /* This gives 5% accuracy with second resolution */
            steps = 0.0; /* number of steps taken */
            nextstep = 0; /* start at beginning of path */
            sec0 = get_seconds(); /* start timer */
            { /* repeat until collect 20 seconds */
                (i=stride;i!=0;i=i-1) { /* keep samples same */
                    nextstep = 0;
                    do nextstep = x[nextstep]; /* dependency */
                    while (nextstep != 0);
                }
                steps = steps + 1.0; /* count loop iterations */
                sec1 = get_seconds(); /* end timer */
            } while ((sec1 - sec0) < 20.0); /* collect 20 seconds */
            sec = sec1 - sec0;

            /* Repeat empty loop to loop subtract overhead */
            tsteps = 0.0; /* used to match no. while iterations */
            sec0 = get_seconds(); /* start timer */
            { /* repeat until same no. iterations as above */
                (i=stride;i!=0;i=i-1) { /* keep samples same */
                    index = 0;
                    do index = index + stride;
                    while (index < csize);
                }
                tsteps = tsteps + 1.0;
                sec1 = get_seconds(); /* - overhead */
            } while (tsteps<steps); /* until = no. iterations */
            sec = sec - (sec1 - sec0);
            loadtime = (sec*1e9)/(steps*csize);
            /* write out results in .csv format for Excel */
            printf("%4.1f,", (loadtime<0.1) ? 0.1 : loadtime);
        }; /* end of inner for loop */
        printf("\n");
    }; /* end of outer for loop */
    return 0;
}

```

Figure 2.32 C program for evaluating memory system.

Visual C++. It can be downloaded from http://www.hpl.hp.com/research/cacti/aca_ch2_cs2.c.

The preceding program assumes that program addresses track physical addresses, which is true on the few machines that use virtually addressed caches, such as the Alpha 21264. In general, virtual addresses tend to follow physical addresses shortly after rebooting, so you may need to reboot the machine in order to get smooth lines in your results. To answer the following questions, assume that the sizes of all components of the memory hierarchy are powers of 2. Assume that the size of the page is much larger than the size of a block in a second-level cache (if there is one) and that the size of a second-level cache block is greater than or equal to the size of a block in a first-level cache. An example of the output of the program is plotted in Figure 2.33; the key lists the size of the array that is exercised.

- 2.4 [12/12/12/10/12] <2.6> Using the sample program results in Figure 2.33:
- [12] <2.6> What are the overall size and block size of the second-level cache?
 - [12] <2.6> What is the miss penalty of the second-level cache?
 - [12] <2.6> What is the associativity of the second-level cache?
 - [10] <2.6> What is the size of the main memory?
 - [12] <2.6> What is the paging time if the page size is 4 KB?

Figure 2.33 Sample results from program in Figure 2.32.

- 2.5 [12/15/15/20] <2.6> If necessary, modify the code in [Figure 2.32](#) to measure the following system characteristics. Plot the experimental results with elapsed time on the y-axis and the memory stride on the x-axis. Use logarithmic scales for both axes, and draw a line for each cache size.
- [12] <2.6> What is the system page size?
 - [15] <2.6> How many entries are there in the TLB?
 - [15] <2.6> What is the miss penalty for the TLB?
 - [20] <2.6> What is the associativity of the TLB?
- 2.6 [20/20] <2.6> In multiprocessor memory systems, lower levels of the memory hierarchy may not be able to be saturated by a single processor but should be able to be saturated by multiple processors working together. Modify the code in [Figure 2.32](#), and run multiple copies at the same time. Can you determine:
- [20] <2.6> How many actual processors are in your computer system and how many system processors are just additional multithreaded contexts?
 - [20] <2.6> How many memory controllers does your system have?
- 2.7 [20] <2.6> Can you think of a way to test some of the characteristics of an instruction cache using a program? *Hint:* The compiler may generate a large number of nonobvious instructions from a piece of code. Try to use simple arithmetic instructions of known length in your instruction set architecture (ISA).

Case Study 3: Studying the Impact of Various Memory System Organizations

Concepts illustrated by this case study

- DDR3 memory systems
- Impact of ranks, banks, row buffers on performance and power
- DRAM timing parameters

A processor chip typically supports a few DDR3 or DDR4 memory channels. We will focus on a single memory channel in this case study and explore how its performance and power are impacted by varying several parameters. Recall that the channel is populated with one or more DIMMs. Each DIMM supports one or more ranks—a rank is a collection of DRAM chips that work in unison to service a single command issued by the memory controller. For example, a rank may be composed of 16 DRAM chips, where each chip deals with a 4-bit input or output on every channel clock edge. Each such chip is referred to as a $\times 4$ (by four) chip. In other examples, a rank may be composed of 8×8 chips or 4×16 chips—note that in each case, a rank can handle data that are being placed on a 64-bit memory channel. A rank is itself partitioned into 8 (DDR3) or 16 (DDR4) banks. Each bank has a row buffer that essentially remembers the last row read out of a bank. Here’s an example of a typical sequence of memory commands when performing a read from a bank:

- (i) The memory controller issues a Precharge command to get the bank ready to access a new row. The precharge is completed after time t_{RP} .
- (ii) The memory controller then issues an Activate command to read the appropriate row out of the bank. The activation is completed after time t_{RCD} and the row is deemed to be part of the row buffer.
- (iii) The memory controller can then issue a column-read or CAS command that places a specific subset of the row buffer on the memory channel. After time CL , the first 64 bits of the data burst are placed on the memory channel. A burst typically includes eight 64-bit transfers on the memory channel, performed on the rising and falling edges of 4 memory clock cycles (referred to as transfer time).
- (iv) If the memory controller wants to then access data in a different row of the bank, referred to as a row buffer miss, it repeats steps (i)–(iii). For now, we will assume that after CL has elapsed, the Precharge in step (i) can be issued; in some cases, an additional delay must be added, but we will ignore that delay here. If the memory controller wants to access another block of data in the same row, referred to as a row buffer hit, it simply issues another CAS command. Two back-to-back CAS commands have to be separated by at least 4 cycles so that the first data transfer is complete before the second data transfer can begin.

Note that a memory controller can issue commands to different banks in successive cycles so that it can perform many memory reads/writes in parallel and it is not sitting idle waiting for t_{RP} , t_{RCD} , and CL to elapse in a single bank. For the subsequent questions, assume that $t_{RP} = t_{RCD} = CL = 13$ ns, and that the memory channel frequency is 1 GHz, that is, a transfer time of 4 ns.

- 2.8 [10] <2.2> What is the read latency experienced by a memory controller on a row buffer miss?
- 2.9 [10] <2.2> What is the latency experienced by a memory controller on a row buffer hit?
- 2.10 [10] <2.2> If the memory channel supports only one bank and the memory access pattern is dominated by row buffer misses, what is the utilization of the memory channel?
- 2.11 [15] <2.2> Assuming a 100% row buffer miss rate, what is the minimum number of banks that the memory channel should support in order to achieve a 100% memory channel utilization?
- 2.12 [10] <2.2> Assuming a 50% row buffer miss rate, what is the minimum number of banks that the memory channel should support in order to achieve a 100% memory channel utilization?
- 2.13 [15] <2.2> Assume that we are executing an application with four threads and the threads exhibit zero spatial locality, that is, a 100% row buffer miss rate. Every 200 ns, each of the four threads simultaneously inserts a read operation into the

memory controller queue. What is the average memory latency experienced if the memory channel supports only one bank? What if the memory channel supported four banks?

- 2.14 [10] <2.2> From these questions, what have you learned about the benefits and downsides of growing the number of banks?
- 2.15 [20] <2.2> Now let's turn our attention to memory power. Download a copy of the Micron power calculator from this link: https://www.micron.com/~media/documents/products/power-calculator/ddr3_power_calc.xlsm. This spreadsheet is preconfigured to estimate the power dissipation in a single 2 Gb \times 8 DDR3 SDRAM memory chip manufactured by Micron. Click on the "Summary" tab to see the power breakdown in a single DRAM chip under default usage conditions (reads occupy the channel for 45% of all cycles, writes occupy the channel for 25% of all cycles, and the row buffer hit rate is 50%). This chip consumes 535 mW, and the breakdown shows that about half of that power is expended in Activate operations, about 38% in CAS operations, and 12% in background power. Next, click on the "System Config" tab. Modify the read/write traffic and the row buffer hit rate and observe how that changes the power profile. For example, what is the decrease in power when channel utilization is 35% (25% reads and 10% writes), or when row buffer hit rate is increased to 80%?
- 2.16 [20] <2.2> In the default configuration, a rank consists of eight \times 8 2 Gb DRAM chips. A rank can also comprise 16×4 chips or 4×16 chips. You can also vary the capacity of each DRAM chip—1 Gb, 2 Gb, and 4 Gb. These selections can be made in the "DDR3 Config" tab of the Micron power calculator. Tabulate the total power consumed for each rank organization. What is the most power-efficient approach to constructing a rank of a given capacity?

Exercises

- 2.17 [12/12/15] <2.3> The following questions investigate the impact of small and simple caches using CACTI and assume a 65 nm (0.065 μ m) technology. (CACTI is available in an online form at <http://quid.hpl.hp.com:9081/cacti/>.)
- [12] <2.3> Compare the access times of 64 KB caches with 64-byte blocks and a single bank. What are the relative access times of two-way and four-way set associative caches compared to a direct mapped organization?
 - [12] <2.3> Compare the access times of four-way set associative caches with 64-byte blocks and a single bank. What are the relative access times of 32 and 64 KB caches compared to a 16 KB cache?
 - [15] <2.3> For a 64 KB cache, find the cache associativity between 1 and 8 with the lowest average memory access time given that misses per instruction for a certain workload suite is 0.00664 for direct-mapped, 0.00366 for two-way set associative, 0.000987 for four-way set associative, and 0.000266 for eight-way set associative cache. Overall, there are 0.3 data references per instruction. Assume cache misses take 10 ns in all models. To calculate the hit time in

cycles, assume the cycle time output using CACTI, which corresponds to the maximum frequency a cache can operate without any bubbles in the pipeline.

- 2.18 [12/15/15/10] <2.3> You are investigating the possible benefits of a way-predicting L1 cache. Assume that a 64 KB four-way set associative single-banked L1 data cache is the cycle time limiter in a system. For an alternative cache organization, you are considering a way-predicted cache modeled as a 64 KB direct-mapped cache with 80% prediction accuracy. Unless stated otherwise, assume that a mispredicted way access that hits in the cache takes one more cycle. Assume the miss rates and the miss penalties in question 2.8 part (c).
- a. [12] <2.3> What is the average memory access time of the current cache (in cycles) versus the way-predicted cache?
 - b. [15] <2.3> If all other components could operate with the faster way-predicted cache cycle time (including the main memory), what would be the impact on performance from using the way-predicted cache?
 - c. [15] <2.3> Way-predicted caches have usually been used only for instruction caches that feed an instruction queue or buffer. Imagine that you want to try out way prediction on a data cache. Assume that you have 80% prediction accuracy and that subsequent operations (e.g., data cache access of other instructions, dependent operations) are issued assuming a correct way prediction. Thus a way misprediction necessitates a pipe flush and replay trap, which requires 15 cycles. Is the change in average memory access time per load instruction with data cache way prediction positive or negative, and how much is it?
 - d. [10] <2.3> As an alternative to way prediction, many large associative L2 caches serialize tag and data access so that only the required dataset array needs to be activated. This saves power but increases the access time. Use CACTI's detailed web interface for a 0.065 m process 1 MB four-way set associative cache with 64-byte blocks, 144 bits read out, 1 bank, only 1 read/write port, 30 bit tags, and ITRS-HP technology with global wires. What is the ratio of the access times for serializing tag and data access compared to parallel access?
- 2.19 [10/12] <2.3> You have been asked to investigate the relative performance of a banked versus pipelined L1 data cache for a new microprocessor. Assume a 64 KB two-way set associative cache with 64-byte blocks. The pipelined cache would consist of three pipe stages, similar in capacity to the Alpha 21264 data cache. A banked implementation would consist of two 32 KB two-way set associative banks. Use CACTI and assume a 65 nm (0.065 m) technology to answer the following questions. The cycle time output in the web version shows at what frequency a cache can operate without any bubbles in the pipeline.
- a. [10] <2.3> What is the cycle time of the cache in comparison to its access time, and how many pipe stages will the cache take up (to two decimal places)?
 - b. [12] <2.3> Compare the area and total dynamic read energy per access of the pipelined design versus the banked design. State which takes up less area and which requires more power, and explain why that might be.

- 2.20 [12/15] <2.3> Consider the usage of critical word first and early restart on L2 cache misses. Assume a 1 MB L2 cache with 64-byte blocks and a refill path that is 16 bytes wide. Assume that the L2 can be written with 16 bytes every 4 processor cycles, the time to receive the first 16 byte block from the memory controller is 120 cycles, each additional 16 byte block from main memory requires 16 cycles, and data can be bypassed directly into the read port of the L2 cache. Ignore any cycles to transfer the miss request to the L2 cache and the requested data to the L1 cache.
- [12] <2.3> How many cycles would it take to service an L2 cache miss with and without critical word first and early restart?
 - [15] <2.3> Do you think critical word first and early restart would be more important for L1 caches or L2 caches, and what factors would contribute to their relative importance?
- 2.21 [12/12] <2.3> You are designing a write buffer between a write-through L1 cache and a write-back L2 cache. The L2 cache write data bus is 16 B wide and can perform a write to an independent cache address every four processor cycles.
- [12] <2.3> How many bytes wide should each write buffer entry be?
 - [15] <2.3> What speedup could be expected in the steady state by using a merging write buffer instead of a nonmerging buffer when zeroing memory by the execution of 64-bit stores if all other instructions could be issued in parallel with the stores and the blocks are present in the L2 cache?
 - [15] <2.3> What would the effect of possible L1 misses be on the number of required write buffer entries for systems with blocking and nonblocking caches?
- 2.22 [20] <2.1, 2.2, 2.3> A cache acts as a filter. For example, for every 1000 instructions of a program, an average of 20 memory accesses may exhibit low enough locality that they cannot be serviced by a 2 MB cache. The 2 MB cache is said to have an MPKI (misses per thousand instructions) of 20, and this will be largely true regardless of the smaller caches that precede the 2 MB cache. Assume the following cache/latency/MPKI values: 32 KB/1/100, 128 KB/2/80, 512 KB/4/50, 2 MB/8/40, 8 MB/16/10. Assume that accessing the off-chip memory system requires 200 cycles on average. For the following cache configurations, calculate the average time spent accessing the cache hierarchy. What do you observe about the downsides of a cache hierarchy that is too shallow or too deep?
- 32 KB L1; 8 MB L2; off-chip memory
 - 32 KB L1; 512 KB L2; 8 MB L3; off-chip memory
 - 32 KB L1; 128 KB L2; 2 MB L3; 8 MB L4; off-chip memory
- 2.23 [15] <2.1, 2.2, 2.3> Consider a 16 MB 16-way L3 cache that is shared by two programs A and B. There is a mechanism in the cache that monitors cache miss rates for each program and allocates 1–15 ways to each program such that the overall number of cache misses is reduced. Assume that program A has an MPKI of 100 when it is assigned 1 MB of the cache. Each additional 1 MB assigned to program

A reduces the MPKI by 1. Program B has an MPKI of 50 when it is assigned 1 MB of cache; each additional 1 MB assigned to program B reduces its MPKI by 2. What is the best allocation of ways to programs A and B?

- 2.24 [20] <2.1, 2.6> You are designing a PMD and optimizing it for low energy. The core, including an 8 KB L1 data cache, consumes 1 W whenever it is not in hibernation. If the core has a perfect L1 cache hit rate, it achieves an average CPI of 1 for a given task, that is, 1000 cycles to execute 1000 instructions. Each additional cycle accessing the L2 and beyond adds a stall cycle for the core. Based on the following specifications, what is the size of L2 cache that achieves the lowest energy for the PMD (core, L1, L2, memory) for that given task?
- The core frequency is 1 GHz, and the L1 has an MPKI of 100.
 - A 256 KB L2 has a latency of 10 cycles, an MPKI of 20, a background power of 0.2 W, and each L2 access consumes 0.5 nJ.
 - A 1 MB L2 has a latency of 20 cycles, an MPKI of 10, a background power of 0.8 W, and each L2 access consumes 0.7 nJ.
 - The memory system has an average latency of 100 cycles, a background power of 0.5 W, and each memory access consumes 35 nJ.
- 2.25 [15] <2.1, 2.6> You are designing a PMD that is optimized for low power. Qualitatively explain the impact on cache hierarchy (L2 and memory) power and overall application energy if you design an L2 cache with:
- Small block size
 - Small cache size
 - High associativity
- 2.30 [10/10] <2.1, 2.2, 2.3> The ways of a set can be viewed as a priority list, ordered from high priority to low priority. Every time the set is touched, the list can be reorganized to change block priorities. With this view, cache management policies can be decomposed into three sub-policies: Insertion, Promotion, and Victim Selection. Insertion defines where newly fetched blocks are placed in the priority list. Promotion defines how a block's position in the list is changed every time it is touched (a cache hit). Victim Selection defines which entry of the list is evicted to make room for a new block when there is a cache miss.
- Can you frame the LRU cache policy in terms of the Insertion, Promotion, and Victim Selection sub-policies?
 - Can you define other Insertion and Promotion policies that may be competitive and worth exploring further?
- 2.31 [15] <2.1, 2.3> In a processor that is running multiple programs, the last-level cache is typically shared by all the programs. This leads to interference, where one program's behavior and cache footprint can impact the cache available to other programs. First, this is a problem from a quality-of-service (QoS) perspective, where the interference leads to a program receiving fewer resources and lower

performance than promised, say by the operator of a cloud service. Second, this is a problem in terms of privacy. Based on the interference it sees, a program can infer the memory access patterns of other programs. This is referred to as a timing channel, a form of information leakage from one program to others that can be exploited to compromise data privacy or to reverse-engineer a competitor's algorithm. What policies can you add to your last-level cache so that the behavior of one program is immune to the behavior of other programs sharing the cache?

- 2.32 [15] <2.3> A large multimegabyte L3 cache can take tens of cycles to access because of the long wires that have to be traversed. For example, it may take 20 cycles to access a 16 MB L3 cache. Instead of organizing the 16 MB cache such that every access takes 20 cycles, we can organize the cache so that it is an array of smaller cache banks. Some of these banks may be closer to the processor core, while others may be further. This leads to nonuniform cache access (NUCA), where 2 MB of the cache may be accessible in 8 cycles, the next 2 MB in 10 cycles, and so on until the last 2 MB is accessed in 22 cycles. What new policies can you introduce to maximize performance in a NUCA cache?
- 2.33 [10/10/10] <2.2> Consider a desktop system with a processor connected to a 2 GB DRAM with *error-correcting code* (ECC). Assume that there is only one memory channel of width 72 bits (64 bits for data and 8 bits for ECC).
- [10] <2.2> How many DRAM chips are on the DIMM if 1 Gb DRAM chips are used, and how many data I/Os must each DRAM have if only one DRAM connects to each DIMM data pin?
 - [10] <2.2> What burst length is required to support 32 B L2 cache blocks?
 - [10] <2.2> Calculate the peak bandwidth for DDR2-667 and DDR2-533 DIMMs for reads from an active page excluding the ECC overhead.
- 2.34 [10/10] <2.2> A sample DDR2 SDRAM timing diagram is shown in [Figure 2.34](#). t_{RCD} is the time required to activate a row in a bank, and column address strobe (CAS) latency (CL) is the number of cycles required to read out a column in a row. Assume that the RAM is on a standard DDR2 DIMM with ECC, having 72 data lines. Also assume burst lengths of 8 that read out 8 bits, or a total of 64 B from the DIMM. Assume $t_{\text{RCD}} = \text{CAS (or CL) clock_frequency}$, and $\text{clock_frequency} = \text{transfers_per_second}/2$. The on-chip latency

Figure 2.34 DDR2 SDRAM timing diagram.

on a cache miss through levels 1 and 2 and back, not including the DRAM access, is 20 ns.

- a. [10] <2.2> How much time is required from presentation of the activate command until the last requested bit of data from the DRAM transitions from valid to invalid for the DDR2-667 1 Gb CL=5 DIMM? Assume that for every request, we automatically prefetch another adjacent cache line in the same page.
 - b. [10] <2.2> What is the relative latency when using the DDR2-667 DIMM of a read requiring a bank activate versus one to an already open page, including the time required to process the miss inside the processor?
- 2.35 [15] <2.2> Assume that a DDR2-667 2 GB DIMM with CL=5 is available for 130 and a DDR2-533 2 GB DIMM with CL=4 is available for 100. Assume that two DIMMs are used in a system, and the rest of the system costs 800. Consider the performance of the system using the DDR2-667 and DDR2-533 DIMMs on a workload with 3.33 L2 misses per 1K instructions, and assume that 80% of all DRAM reads require an activate. What is the cost-performance of the entire system when using the different DIMMs, assuming only one L2 miss is outstanding at a time and an in-order core with a CPI of 1.5 not including L2 cache miss memory access time?
- 2.36 [12] <2.2> You are provisioning a server with eight-core 3 GHz CMP that can execute a workload with an overall CPI of 2.0 (assuming that L2 cache miss refills are not delayed). The L2 cache line size is 32 bytes. Assuming the system uses DDR2-667 DIMMs, how many independent memory channels should be provided so the system is not limited by memory bandwidth if the bandwidth required is sometimes twice the average? The workloads incur, on average, 6.67 L2 misses per 1 K instructions.
- 2.37 [15] <2.2> Consider a processor that has four memory channels. Should consecutive memory blocks be placed in the same bank, or should they be placed in different banks on different channels?
- 2.38 [12/12] <2.2> A large amount (more than a third) of DRAM power can be due to page activation (see <http://download.micron.com/pdf/technotes/ddr2/TN4704.pdf> and <http://www.micron.com/systemcalc>). Assume you are building a system with 2 GB of memory using either 8-bank 2 Gb \times 8 DDR2 DRAMs or 8-bank 1 Gb \times 8 DRAMs, both with the same speed grade. Both use a page size of 1 KB, and the last-level cache line size is 64 bytes. Assume that DRAMs that are not active are in precharged standby and dissipate negligible power. Assume that the time to transition from standby to active is not significant.
- a. [12] <2.2> Which type of DRAM would be expected to provide the higher system performance? Explain why.
 - b. [12] <2.2> How does a 2 GB DIMM made of 1 Gb \times 8 DDR2 DRAMs compare with a DIMM with similar capacity made of 1 Gb \times 4 DDR2 DRAMs in terms of power?

- 2.39 [20/15/12] <2.2> To access data from a typical DRAM, we first have to activate the appropriate row. Assume that this brings an entire page of size 8 KB to the row buffer. Then we select a particular column from the row buffer. If subsequent accesses to DRAM are to the same page, then we can skip the activation step; otherwise, we have to close the current page and precharge the bitlines for the next activation. Another popular DRAM policy is to proactively close a page and precharge bitlines as soon as an access is over. Assume that every read or write to DRAM is of size 64 bytes and DDR bus latency (data from Figure 2.33) for sending 512 bits is T_{ddr} .
- [20] <2.2> Assuming DDR2-667, if it takes five cycles to precharge, five cycles to activate, and four cycles to read a column, for what value of the row buffer hit rate (r) will you choose one policy over another to get the best access time? Assume that every access to DRAM is separated by enough time to finish a random new access.
 - [15] <2.2> If 10% of the total accesses to DRAM happen back to back or contiguously without any time gap, how will your decision change?
 - [12] <2.2> Calculate the difference in average DRAM energy per access between the two policies using the previously calculated row buffer hit rate. Assume that precharging requires 2 nJ and activation requires 4 nJ and that 100 pJ/bit are required to read or write from the row buffer.
- 2.40 [15] <2.2> Whenever a computer is idle, we can either put it in standby (where DRAM is still active) or we can let it hibernate. Assume that, to hibernate, we have to copy just the contents of DRAM to a nonvolatile medium such as Flash. If reading or writing a cache line of size 64 bytes to Flash requires 2.56 J and DRAM requires 0.5 nJ, and if idle power consumption for DRAM is 1.6 W (for 8 GB), how long should a system be idle to benefit from hibernating? Assume a main memory of size 8 GB.
- 2.41 [10/10/10/10/10] <2.4> Virtual machines (VMs) have the potential for adding many beneficial capabilities to computer systems, such as improved total cost of ownership (TCO) or availability. Could VMs be used to provide the following capabilities? If so, how could they facilitate this?
- [10] <2.4> Test applications in production environments using development machines?
 - [10] <2.4> Quick redeployment of applications in case of disaster or failure?
 - [10] <2.4> Higher performance in I/O-intensive applications?
 - [10] <2.4> Fault isolation between different applications, resulting in higher availability for services?
 - [10] <2.4> Performing software maintenance on systems while applications are running without significant interruption?
- 2.42 [10/10/12/12] <2.4> Virtual machines can lose performance from a number of events, such as the execution of privileged instructions, TLB misses, traps, and I/O.

Benchmark	Native	Pure	Para
Null call	0.04	0.96	0.50
Null I/O	0.27	6.32	2.91
Stat	1.10	10.69	4.14
Open/close	1.99	20.43	7.71
Install signal handler	0.33	7.34	2.89
Handle signal	1.69	19.26	2.36
Fork	56.00	513.00	164.00
Exec	316.00	2084.00	578.00
Fork + exec sh	1451.00	7790.00	2360.00

Figure 2.35 Early performance of various system calls under native execution, pure virtualization, and paravirtualization.

These events are usually handled in system code. Thus one way of estimating the slowdown when running under a VM is the percentage of application execution time in system versus user mode. For example, an application spending 10% of its execution in system mode might slow down by 60% when running on a VM. [Figure 2.35](#) lists the early performance of various system calls under native execution, pure virtualization, and paravirtualization for LMBench using Xen on an Itanium system with times measured in microseconds (courtesy of Matthew Chapman of the University of New South Wales).

- a. [10] <2.4> What types of programs would be expected to have smaller slowdowns when running under VMs?
 - b. [10] <2.4> If slowdowns were linear as a function of system time, given the preceding slowdown, how much slower would a program spending 20% of its execution in system time be expected to run?
 - c. [12] <2.4> What is the median slowdown of the system calls in the table above under pure virtualization and paravirtualization?
 - d. [12] <2.4> Which functions in the table above have the largest slowdowns? What do you think the cause of this could be?
- 2.43 [12] <2.4> Popek and Goldberg's definition of a virtual machine said that it would be indistinguishable from a real machine except for its performance. In this question, we will use that definition to find out if we have access to native execution on a processor or are running on a virtual machine. The Intel VT-x technology effectively provides a second set of privilege levels for the use of the virtual machine. What would a virtual machine running on top of another virtual machine have to do, assuming VT-x technology?
- 2.44 [20/25] <2.4> With the adoption of virtualization support on the x86 architecture, virtual machines are actively evolving and becoming mainstream. Compare and contrast the Intel VT-x and AMD's AMD-V virtualization technologies.

(Information on AMD-V can be found at <http://sites.amd.com/us/business/it-solutions/virtualization/Pages/resources.aspx>.)

- a. [20] <2.4> Which one could provide higher performance for memory-intensive applications with large memory footprints?
 - b. [25] <2.4> Information on AMD's IOMMU support for virtualized I/O can be found at <http://developer.amd.com/documentation/articles/pages/892006101.aspx>. What do Virtualization Technology and an input/output memory management unit (IOMMU) do to improve virtualized I/O performance?
- 2.45 [30] <2.2, 2.3> Since instruction-level parallelism can also be effectively exploited on in-order superscalar processors and *very long instruction word* (VLIW) processors with speculation, one important reason for building an out-of-order (OOO) superscalar processor is the ability to tolerate unpredictable memory latency caused by cache misses. Thus you can think about hardware supporting OOO issue as being part of the memory system. Look at the floorplan of the Alpha 21264 in Figure 2.36 to find the relative area of the integer and floating-point issue queues and mappers versus the caches. The queues schedule instructions for issue,

Figure 2.36 Floorplan of the Alpha 21264 [Kessler 1999].

and the mappers rename register specifiers. Therefore these are necessary additions to support OOO issue. The 21264 only has L1 data and instruction caches on chip, and they are both 64 KB two-way set associative. Use an OOO superscalar simulator such as SimpleScalar (<http://www.cs.wisc.edu/~mscalar/simplescalar.html>) on memory-intensive benchmarks to find out how much performance is lost if the area of the issue queues and mappers is used for additional L1 data cache area in an in-order superscalar processor, instead of OOO issue in a model of the 21264. Make sure the other aspects of the machine are as similar as possible to make the comparison fair. Ignore any increase in access or cycle time from larger caches and effects of the larger data cache on the floorplan of the chip. (Note that this comparison will not be totally fair, as the code will not have been scheduled for the in-order processor by the compiler.)

- 2.46 [15] <2.2, 2.7> As discussed in [Section 2.7](#), the Intel i7 processor has an aggressive prefetcher. What are potential disadvantages in designing a prefetcher that is extremely aggressive?
- 2.47 [20/20/20] <2.6> The Intel performance analyzer VTune can be used to make many measurements of cache behavior. A free evaluation version of VTune on both Windows and Linux can be downloaded from <http://software.intel.com/en-us/articles/intel-vtune-amplifier-xe/>. The program (`aca_ch2_cs2.c`) used in Case Study 2 has been modified so that it can work with VTune out of the box on Microsoft Visual C++. The program can be downloaded from http://www.hpl.hp.com/research/cacti/aca_ch2_cs2_vtune.c. Special VTune functions have been inserted to exclude initialization and loop overhead during the performance analysis process. Detailed VTune setup directions are given in the README section in the program. The program keeps looping for 20 seconds for every configuration. In the following experiment, you can find the effects of data size on cache and overall processor performance. Run the program in VTune on an Intel processor with the input dataset sizes of 8 KB, 128 KB, 4 MB, and 32 MB, and keep a stride of 64 bytes (stride one cache line on Intel i7 processors). Collect statistics on overall performance and L1 data cache, L2, and L3 cache performance.
- [20] <2.6> List the number of misses per 1K instruction of L1 data cache, L2, and L3 for each dataset size and your processor model and speed. Based on the results, what can you say about the L1 data cache, L2, and L3 cache sizes on your processor? Explain your observations.
 - [20] <2.6> List the *instructions per clock* (IPC) for each dataset size and your processor model and speed. Based on the results, what can you say about the L1, L2, and L3 miss penalties on your processor? Explain your observations.
 - [20] <2.6> Run the program in VTune with input dataset size of 8 KB and 128 KB on an Intel OOO processor. List the number of L1 data cache and L2 cache misses per 1K instructions and the CPI for both configurations. What can you say about the effectiveness of memory latency hiding techniques in high-performance OOO processors? *Hint:* You need to find the L1 data cache miss latency for your processor. For recent Intel i7 processors, it is approximately 11 cycles.

Instruction-Level Parallelism and Its Exploitation

"Who's first?"

"America."

"Who's second?"

"Sir, there is no second."

Dialog between two observers of the sailing race in 1851, later named "The America's Cup," which was the inspiration for John Cocke's naming of an IBM research processor as "America," the first superscalar processor, and a precursor to the PowerPC.

Thus, the IA-64 gambles that, in the future, power will not be the critical limitation, and massive resources...will not penalize clock speed, path length, or CPI factors. My view is clearly skeptical...

Marty Hopkins (2000), IBM Fellow and Early RISC pioneer commenting in 2000 on the new Intel Itanium, a joint development of Intel and HP. The Itanium used a static ILP approach (see Appendix H) and was a massive investment for Intel. It never accounted for more than 0.5% of Intel's microprocessor sales.

3.1

Instruction-Level Parallelism: Concepts and Challenges

All processors since about 1985 have used pipelining to overlap the execution of instructions and improve performance. This potential overlap among instructions is called *instruction-level parallelism* (ILP), because the instructions can be evaluated in parallel. In this chapter and Appendix H, we look at a wide range of techniques for extending the basic pipelining concepts by increasing the amount of parallelism exploited among instructions.

This chapter is at a considerably more advanced level than the material on basic pipelining in [Appendix C](#). If you are not thoroughly familiar with the ideas in [Appendix C](#), you should review that appendix before venturing into this chapter.

We start this chapter by looking at the limitation imposed by data and control hazards and then turn to the topic of increasing the ability of the compiler and the processor to exploit parallelism. These sections introduce a large number of concepts, which we build on throughout this chapter and the next. While some of the more basic material in this chapter could be understood without all of the ideas in the first two sections, this basic material is important to later sections of this chapter.

There are two largely separable approaches to exploiting ILP: (1) an approach that relies on hardware to help discover and exploit the parallelism dynamically, and (2) an approach that relies on software technology to find parallelism statically at compile time. Processors using the dynamic, hardware-based approach, including all recent Intel and many ARM processors, dominate in the desktop and server markets. In the personal mobile device market, the same approaches are used in processors found in tablets and high-end cell phones. In the IOT space, where power and cost constraints dominate performance goals, designers exploit lower levels of instruction-level parallelism. Aggressive compiler-based approaches have been attempted numerous times beginning in the 1980s and most recently in the Intel Itanium series, introduced in 1999. Despite enormous efforts, such approaches have been successful only in domain-specific environments or in well-structured scientific applications with significant data-level parallelism.

In the past few years, many of the techniques developed for one approach have been exploited within a design relying primarily on the other. This chapter introduces the basic concepts and both approaches. A discussion of the limitations on ILP approaches is included in this chapter, and it was such limitations that directly led to the movement toward multicore. Understanding the limitations remains important in balancing the use of ILP and thread-level parallelism.

In this section, we discuss features of both programs and processors that limit the amount of parallelism that can be exploited among instructions, as well as the critical mapping between program structure and hardware structure, which is key to understanding whether a program property will actually limit performance and under what circumstances.

The value of the CPI (cycles per instruction) for a pipelined processor is the sum of the base CPI and all contributions from stalls:

$$\text{Pipeline CPI} = \text{Ideal pipeline CPI} + \text{Structural stalls} + \text{Data hazard stalls} + \text{Control stalls}$$

Technique	Reduces	Section
Forwarding and bypassing	Potential data hazard stalls	C.2
Simple branch scheduling and prediction	Control hazard stalls	C.2
Basic compiler pipeline scheduling	Data hazard stalls	C.2, 3.2
Basic dynamic scheduling (scoreboarding)	Data hazard stalls from true dependences	C.7
Loop unrolling	Control hazard stalls	3.2
Advanced branch prediction	Control stalls	3.3
Dynamic scheduling with renaming	Stalls from data hazards, output dependences, and antidependences	3.4
Hardware speculation	Data hazard and control hazard stalls	3.6
Dynamic memory disambiguation	Data hazard stalls with memory	3.6
Issuing multiple instructions per cycle	Ideal CPI	3.7, 3.8
Compiler dependence analysis, software pipelining, trace scheduling	Ideal CPI, data hazard stalls	H.2, H.3
Hardware support for compiler speculation	Ideal CPI, data hazard stalls, branch hazard stalls	H.4, H.5

Figure 3.1 The major techniques examined in [Appendix C](#), Chapter 3, and [Appendix H](#) are shown together with the component of the CPI equation that the technique affects.

The *ideal pipeline CPI* is a measure of the maximum performance attainable by the implementation. By reducing each of the terms of the right-hand side, we decrease the overall pipeline CPI or, alternatively, increase the IPC (instructions per clock). The preceding equation allows us to characterize various techniques by what component of the overall CPI a technique reduces. [Figure 3.1](#) shows the techniques we examine in this chapter and in [Appendix H](#), as well as the topics covered in the introductory material in [Appendix C](#). In this chapter, we will see that the techniques we introduce to decrease the ideal pipeline CPI can increase the importance of dealing with hazards.

What Is Instruction-Level Parallelism?

All the techniques in this chapter exploit parallelism among instructions. The amount of parallelism available within a *basic block*—a straight-line code sequence with no branches in except to the entry and no branches out except at the exit—is quite small. For typical RISC programs, the average dynamic branch frequency is often between 15% and 25%, meaning that between three and six instructions execute between a pair of branches. Because these instructions are likely to depend upon one another, the amount of overlap we can exploit within a basic block is likely to be less than the average basic block size. To obtain substantial performance enhancements, we must exploit ILP across multiple basic blocks.

The simplest and most common way to increase the ILP is to exploit parallelism among iterations of a loop. This type of parallelism is often called *loop-level*

parallelism. Here is a simple example of a loop that adds two 1000-element arrays and is completely parallel:

```
for (i=0; i<=999; i=i+1)
    x[i] = x[i] + y[i];
```

Every iteration of the loop can overlap with any other iteration, although within each loop iteration, there is little or no opportunity for overlap.

We will examine a number of techniques for converting such loop-level parallelism into instruction-level parallelism. Basically, such techniques work by unrolling the loop either statically by the compiler (as in the next section) or dynamically by the hardware (as in [Sections 3.5 and 3.6](#)).

An important alternative method for exploiting loop-level parallelism is the use of SIMD in both vector processors and graphics processing units (GPUs), both of which are covered in [Chapter 4](#). A SIMD instruction exploits data-level parallelism by operating on a small to moderate number of data items in parallel (typically two to eight). A vector instruction exploits data-level parallelism by operating on many data items in parallel using both parallel execution units and a deep pipeline. For example, the preceding code sequence, which in simple form requires seven instructions per iteration (two loads, an add, a store, two address updates, and a branch) for a total of 7000 instructions, might execute in one-quarter as many instructions in some SIMD architecture where four data items are processed per instruction. On some vector processors, this sequence might take only four instructions: two instructions to load the vectors *x* and *y* from memory, one instruction to add the two vectors, and an instruction to store back the result vector. Of course, these instructions would be pipelined and have relatively long latencies, but these latencies may be overlapped.

Data Dependences and Hazards

Determining how one instruction depends on another is critical to determining how much parallelism exists in a program and how that parallelism can be exploited. In particular, to exploit instruction-level parallelism, we must determine which instructions can be executed in parallel. If two instructions are *parallel*, they can execute simultaneously in a pipeline of arbitrary depth without causing any stalls, assuming the pipeline has sufficient resources (and thus no structural hazards exist). If two instructions are dependent, they are not parallel and must be executed in order, although they may often be partially overlapped. The key in both cases is to determine whether an instruction is dependent on another instruction.

Data Dependences

There are three different types of dependences: *data dependences* (also called true data dependences), *name dependences*, and *control dependences*. An instruction *j* is *data-dependent* on instruction *i* if either of the following holds:

- Instruction i produces a result that may be used by instruction j .
- Instruction j is data-dependent on instruction k , and instruction k is data-dependent on instruction i .

The second condition simply states that one instruction is dependent on another if there exists a chain of dependences of the first type between the two instructions. This dependence chain can be as long as the entire program. Note that a dependence within a single instruction (such as `add x1, x1, x1`) is not considered a dependence.

For example, consider the following RISC-V code sequence that increments a vector of values in memory (starting at `0(x1)` ending with the last element at `0(x2)`) by a scalar in register `f2`.

```
Loop: fld      f0,0(x1)      //f0=array element
      fadd.d   f4,f0,f2      //add scalar in f2
      fsd      f4,0(x1)      //store result
      addi     x1,x1,-8       //decrement pointer 8 bytes
      bne      x1,x2,Loop    //branch x1≠x2
```

The data dependences in this code sequence involve both floating-point data:

```
Loop: fld      f0,0(x1)      //f0=array element
      fadd.d   f4,f0,f2      //add scalar in f2
      fsd      f4,0(x1)      //store result
```

and integer data:

```
addi     x1,x1,-8           //decrement pointer
                                   //8 bytes (per DW)
bne      x1,x2,Loop         //branch x1≠x2
```

In both of the preceding dependent sequences, as shown by the arrows, each instruction depends on the previous one. The arrows here and in following examples show the order that must be preserved for correct execution. The arrow points from an instruction that must precede the instruction that the arrowhead points to.

If two instructions are data-dependent, they must execute in order and cannot execute simultaneously or be completely overlapped. The dependence implies that there would be a chain of one or more data hazards between the two instructions. (See [Appendix C](#) for a brief description of data hazards, which we will define precisely in a few pages.) Executing the instructions simultaneously will cause a processor with pipeline interlocks (and a pipeline depth longer than the distance between the instructions in cycles) to detect a hazard and stall, thereby reducing or eliminating the overlap. In a processor without interlocks that relies on compiler scheduling, the compiler cannot schedule dependent instructions in such a way that

they completely overlap because the program will not execute correctly. The presence of a data dependence in an instruction sequence reflects a data dependence in the source code from which the instruction sequence was generated. The effect of the original data dependence must be preserved.

Dependences are a property of *programs*. Whether a given dependence results in an actual hazard being detected and whether that hazard actually causes a stall are properties of the *pipeline organization*. This difference is critical to understanding how instruction-level parallelism can be exploited.

A data dependence conveys three things: (1) the possibility of a hazard, (2) the order in which results must be calculated, and (3) an upper bound on how much parallelism can possibly be exploited. Such limits are explored in a pitfall on [page 262](#) and in Appendix H in more detail.

Because a data dependence can limit the amount of instruction-level parallelism we can exploit, a major focus of this chapter is overcoming these limitations. A dependence can be overcome in two different ways: (1) maintaining the dependence but avoiding a hazard, and (2) eliminating a dependence by transforming the code. Scheduling the code is the primary method used to avoid a hazard without altering a dependence, and such scheduling can be done both by the compiler and by the hardware.

A data value may flow between instructions either through registers or through memory locations. When the data flow occurs through a register, detecting the dependence is straightforward because the register names are fixed in the instructions, although it gets more complicated when branches intervene and correctness concerns force a compiler or hardware to be conservative.

Dependences that flow through memory locations are more difficult to detect because two addresses may refer to the same location but look different: For example, $100(\times 4)$ and $20(\times 6)$ may be identical memory addresses. In addition, the effective address of a load or store may change from one execution of the instruction to another (so that $20(\times 4)$ and $20(\times 4)$ may be different), further complicating the detection of a dependence.

In this chapter, we examine hardware for detecting data dependences that involve memory locations, but we will see that these techniques also have limitations. The compiler techniques for detecting such dependences are critical in uncovering loop-level parallelism.

Name Dependences

The second type of dependence is a *name dependence*. A name dependence occurs when two instructions use the same register or memory location, called a *name*, but there is no flow of data between the instructions associated with that name. There are two types of name dependences between an instruction *i* that *precedes* instruction *j* in program order:

1. An *antidependence* between instruction *i* and instruction *j* occurs when instruction *j* writes a register or memory location that instruction *i* reads. The original

ordering must be preserved to ensure that i reads the correct value. In the example on [page 171](#), there is an antidependence between `fsd` and `addi` on register `x1`.

2. An *output dependence* occurs when instruction i and instruction j write the same register or memory location. The ordering between the instructions must be preserved to ensure that the value finally written corresponds to instruction j .

Both antidependences and output dependences are name dependences, as opposed to true data dependences, because there is no value being transmitted between the instructions. Because a name dependence is not a true dependence, instructions involved in a name dependence can execute simultaneously or be reordered, if the name (register number or memory location) used in the instructions is changed so the instructions do not conflict.

This renaming can be more easily done for register operands, where it is called *register renaming*. Register renaming can be done either statically by a compiler or dynamically by the hardware. Before describing dependences arising from branches, let's examine the relationship between dependences and pipeline data hazards.

Data Hazards

A hazard exists whenever there is a name or data dependence between instructions, and they are close enough that the overlap during execution would change the order of access to the operand involved in the dependence. Because of the dependence, we must preserve what is called *program order*—that is, the order that the instructions would execute in if executed sequentially one at a time as determined by the original source program. The goal of both our software and hardware techniques is to exploit parallelism by preserving program order *only where it affects the outcome of the program*. Detecting and avoiding hazards ensures that necessary program order is preserved.

Data hazards, which are informally described in [Appendix C](#), may be classified as one of three types, depending on the order of read and write accesses in the instructions. By convention, the hazards are named by the ordering in the program that must be preserved by the pipeline. Consider two instructions i and j , with i preceding j in program order. The possible data hazards are

- **RAW (read after write)**— j tries to read a source before i writes it, so j incorrectly gets the *old* value. This hazard is the most common type and corresponds to a true data dependence. Program order must be preserved to ensure that j receives the value from i .
- **WAW (write after write)**— j tries to write an operand before it is written by i . The writes end up being performed in the wrong order, leaving the value written by i rather than the value written by j in the destination. This hazard corresponds to an output dependence. WAW hazards are present only in pipelines that write in more than one pipe stage or allow an instruction to proceed even when a previous instruction is stalled.

- **WAR (write after read)**— j tries to write a destination before it is read by i , so i incorrectly gets the *new* value. This hazard arises from an antidependence (or name dependence). WAR hazards cannot occur in most static issue pipelines—even deeper pipelines or floating-point pipelines—because all reads are early (in ID in the pipeline in [Appendix C](#)) and all writes are late (in WB in the pipeline in [Appendix C](#)). A WAR hazard occurs either when there are some instructions that write results early in the instruction pipeline *and* other instructions that read a source late in the pipeline, or when instructions are reordered, as we will see in this chapter.

Note that the RAR (*read after read*) case is not a hazard.

Control Dependences

The last type of dependence is a *control dependence*. A control dependence determines the ordering of an instruction, i , with respect to a branch instruction so that instruction i is executed in correct program order and only when it should be. Every instruction, except for those in the first basic block of the program, is control-dependent on some set of branches, and in general, these control dependences must be preserved to preserve program order. One of the simplest examples of a control dependence is the dependence of the statements in the “then” part of an if statement on the branch. For example, in the code segment

```
if p1 {
    S1;
};
if p2 {
    S2;
}
```

$S1$ is control-dependent on $p1$, and $S2$ is control-dependent on $p2$ but not on $p1$.

In general, two constraints are imposed by control dependences:

1. An instruction that is control-dependent on a branch cannot be moved *before* the branch so that its execution *is no longer controlled* by the branch. For example, we cannot take an instruction from the then portion of an if statement and move it before the if statement.
2. An instruction that is not control-dependent on a branch cannot be moved *after* the branch so that its execution *is controlled* by the branch. For example, we cannot take a statement before the if statement and move it into the then portion.

When processors preserve strict program order, they ensure that control dependences are also preserved. We may be willing to execute instructions that should not have been executed, however, thereby violating the control dependences, *if* we

can do so without affecting the correctness of the program. Thus control dependence is not the critical property that must be preserved. Instead, the two properties critical to program correctness—and normally preserved by maintaining both data and control dependences—are the *exception behavior* and the *data flow*.

Preserving the exception behavior means that any changes in the ordering of instruction execution must not change how exceptions are raised in the program. Often this is relaxed to mean that the reordering of instruction execution must not cause any new exceptions in the program. A simple example shows how maintaining the control and data dependences can prevent such situations. Consider this code sequence:

```

        add  x2,x3,x4
        beq  x2,x0,L1
        ld   x1,0(x2)
L1:
```

In this case, it is easy to see that if we do not maintain the data dependence involving `x2`, we can change the result of the program. Less obvious is the fact that if we ignore the control dependence and move the load instruction before the branch, the load instruction may cause a memory protection exception. Notice that *no data dependence* prevents us from interchanging the `beqz` and the `ld`; it is only the control dependence. To allow us to reorder these instructions (and still preserve the data dependence), we want to just ignore the exception when the branch is taken. In [Section 3.6](#), we will look at a hardware technique, *speculation*, which allows us to overcome this exception problem. Appendix H looks at software techniques for supporting speculation.

The second property preserved by maintenance of data dependences and control dependences is the data flow. The *data flow* is the actual flow of data values among instructions that produce results and those that consume them. Branches make the data flow dynamic because they allow the source of data for a given instruction to come from many points. Put another way, it is insufficient to just maintain data dependences because an instruction may be data-dependent on more than one predecessor. Program order is what determines which predecessor will actually deliver a data value to an instruction. Program order is ensured by maintaining the control dependences.

For example, consider the following code fragment:

```

        add  x1,x2,x3
        beq  x4,x0,L
        sub  x1,x5,x6
L:      ...
        or   x7,x1,x8
```

In this example, the value of `x1` used by the `or` instruction depends on whether the branch is taken or not. Data dependence alone is not sufficient to preserve correctness. The `or` instruction is data-dependent on both the `add` and `sub` instructions, but preserving that order alone is insufficient for correct execution.

Instead, when the instructions execute, the data flow must be preserved: If the branch is not taken, then the value of `x1` computed by the `sub` should be used by the `or`, and if the branch is taken, the value of `x1` computed by the `add` should be used by the `or`. By preserving the control dependence of the `or` on the branch, we prevent an illegal change to the data flow. For similar reasons, the `sub` instruction cannot be moved above the branch. Speculation, which helps with the exception problem, will also allow us to lessen the impact of the control dependence while still maintaining the data flow, as we will see in [Section 3.6](#).

Sometimes we can determine that violating the control dependence cannot affect either the exception behavior or the data flow. Consider the following code sequence:

```

        add    x1,x2,x3
        beq    x12,x0,skip
        sub    x4,x5,x6
        add    x5,x4,x9
skip:    or     x7,x8,x9

```

Suppose we knew that the register destination of the `sub` instruction (`x4`) was unused after the instruction labeled `skip`. (The property of whether a value will be used by an upcoming instruction is called *liveness*.) If `x4` were unused, then changing the value of `x4` just before the branch would not affect the data flow because `x4` would be *dead* (rather than live) in the code region after `skip`. Thus, if `x4` were dead and the existing `sub` instruction could not generate an exception (other than those from which the processor resumes the same process), we could move the `sub` instruction before the branch because the data flow could not be affected by this change.

If the branch is taken, the `sub` instruction will execute and will be useless, but it will not affect the program results. This type of code scheduling is also a form of speculation, often called software speculation, because the compiler is betting on the branch outcome; in this case, the bet is that the branch is usually not taken. More ambitious compiler speculation mechanisms are discussed in [Appendix H](#). Normally, it will be clear when we say speculation or speculative whether the mechanism is a hardware or software mechanism; when it is not clear, it is best to say “hardware speculation” or “software speculation.”

Control dependence is preserved by implementing control hazard detection that causes control stalls. Control stalls can be eliminated or reduced by a variety of hardware and software techniques, which we examine in [Section 3.3](#).

3.2

Basic Compiler Techniques for Exposing ILP

This section examines the use of simple compiler technology to enhance a processor’s ability to exploit ILP. These techniques are crucial for processors that use static issue or static scheduling. Armed with this compiler technology, we will shortly examine the design and performance of processors using static issuing. [Appendix H](#) will investigate more sophisticated compiler and associated hardware schemes designed to enable a processor to exploit more instruction-level parallelism.

Basic Pipeline Scheduling and Loop Unrolling

To keep a pipeline full, parallelism among instructions must be exploited by finding sequences of unrelated instructions that can be overlapped in the pipeline. To avoid a pipeline stall, the execution of a dependent instruction must be separated from the source instruction by a distance in clock cycles equal to the pipeline latency of that source instruction. A compiler's ability to perform this scheduling depends both on the amount of ILP available in the program and on the latencies of the functional units in the pipeline. [Figure 3.2](#) shows the FP unit latencies we assume in this chapter, unless different latencies are explicitly stated. We assume the standard five-stage integer pipeline so that branches have a delay of one clock cycle. We assume that the functional units are fully pipelined or replicated (as many times as the pipeline depth) so that an operation of any type can be issued on every clock cycle and there are no structural hazards.

In this section, we look at how the compiler can increase the amount of available ILP by transforming loops. This example serves both to illustrate an important technique as well as to motivate the more powerful program transformations described in [Appendix H](#). We will rely on the following code segment, which adds a scalar to a vector:

```
for (i=999; i>=0; i=i-1)
    x[i] = x[i] + s;
```

We can see that this loop is parallel by noticing that the body of each iteration is independent. We formalize this notion in [Appendix H](#) and describe how we can test whether loop iterations are independent at compile time. First, let's look at the performance of this loop, which shows how we can use the parallelism to improve its performance for a RISC-V pipeline with the preceding latencies.

The first step is to translate the preceding segment to RISC-V assembly language. In the following code segment, `x1` is initially the address of the element in the array with the highest address, and `f2` contains the scalar value `s`. Register `x2` is precomputed so that `Regs[x2]+8` is the address of the last element to operate on.

Instruction producing result	Instruction using result	Latency in clock cycles
FP ALU op	Another FP ALU op	3
FP ALU op	Store double	2
Load double	FP ALU op	1
Load double	Store double	0

Figure 3.2 Latencies of FP operations used in this chapter. The last column is the number of intervening clock cycles needed to avoid a stall. These numbers are similar to the average latencies we would see on an FP unit. The latency of a floating-point load to a store is 0 because the result of the load can be bypassed without stalling the store. We will continue to assume an integer load latency of 1 and an integer ALU operation latency of 0 (which includes ALU operation to branch).

The straightforward RISC-V code, not scheduled for the pipeline, looks like this:

```

Loop: fld      f0,0(x1)      //f0=array element
      fadd.d   f4,f0,f2      //add scalar in f2
      fsd      f4,0(x1)      //store result
      addi     x1,x1,-8       //decrement pointer
                                //8 bytes (per DW)
      bne      x1,x2,Loop     //branch x1≠x2

```

Let's start by seeing how well this loop will run when it is scheduled on a simple pipeline for RISC-V with the latencies in [Figure 3.2](#).

Example Show how the loop would look on RISC-V, both scheduled and unscheduled, including any stalls or idle clock cycles. Schedule for delays from floating-point operations.

Answer Without any scheduling, the loop will execute as follows, taking nine cycles:

	<u>Clock cycle issued</u>
Loop: fld f0,0(x1)	1
stall	2
fadd.d f4,f0,f2	3
stall	4
stall	5
fsd f4,0(x1)	6
addi x1,x1,-8	7
bne x1,x2,Loop	8

We can schedule the loop to obtain only two stalls and reduce the time to seven cycles:

```

Loop: fld      f0,0(x1)
      addi     x1,x1,-8
      fadd.d   f4,f0,f2
      stall
      stall
      fsd      f4,8(x1)
      bne      x1,x2,Loop

```

The stalls after `fadd.d` are for use by the `fsd`, and repositioning the `addi` prevents the stall after the `fld`.

In the previous example, we complete one loop iteration and store back one array element every seven clock cycles, but the actual work of operating on the array element takes just three (the load, add, and store) of those seven clock cycles.

The remaining four clock cycles consist of loop overhead—the `addi` and `bne`—and two stalls. To eliminate these four clock cycles, we need to get more operations relative to the number of overhead instructions.

A simple scheme for increasing the number of instructions relative to the branch and overhead instructions is *loop unrolling*. Unrolling simply replicates the loop body multiple times, adjusting the loop termination code.

Loop unrolling can also be used to improve scheduling. Because it eliminates the branch, it allows instructions from different iterations to be scheduled together. In this case, we can eliminate the data use stalls by creating additional independent instructions within the loop body. If we simply replicated the instructions when we unrolled the loop, the resulting use of the same registers could prevent us from effectively scheduling the loop. Thus we will want to use different registers for each iteration, increasing the required number of registers.

Example Show our loop unrolled so that there are four copies of the loop body, assuming $x1 - x2$ (that is, the size of the array) is initially a multiple of 32, which means that the number of loop iterations is a multiple of 4. Eliminate any obviously redundant computations and do not reuse any of the registers.

Answer Here is the result after merging the `addi` instructions and dropping the unnecessary `bne` operations that are duplicated during unrolling. Note that `x2` must now be set so that `Regs[x2]+32` is the starting address of the last four elements.

```

Loop: fld      f0,0(x1)
      fadd.d   f4,f0,f2
      fsd      f4,0(x1)      //drop addi & bne
      fld      f6,-8(x1)
      fadd.d   f8,f6,f2
      fsd      f8,-8(x1)    //drop addi & bne
      fld      f0,-16(x1)
      fadd.d   f12,f0,f2
      fsd      f12,-16(x1)  //drop addi & bne
      fld      f14,-24(x1)
      fadd.d   f16,f14,f2
      fsd      f16,-24(x1)
      addi     x1,x1,-32
      bne      x1,x2,Loop

```

We have eliminated three branches and three decrements of `x1`. The addresses on the loads and stores have been compensated to allow the `addi` instructions on `x1` to be merged. This optimization may seem trivial, but it is not; it requires symbolic substitution and simplification. Symbolic substitution and simplification will rearrange expressions so as to allow constants to be collapsed, allowing an expression such as $((i+1)+1)$ to be rewritten as $(i+(1+1))$ and then simplified to $(i+2)$.

We will see more general forms of these optimizations that eliminate dependent computations in Appendix H.

Without scheduling, every FP load or operation in the unrolled loop is followed by a dependent operation and thus will cause a stall. This unrolled loop will run in 26 clock cycles—each `fld` has 1 stall, each `fadd.d` has 2, plus 14 instruction issue cycles—or 6.5 clock cycles for each of the four elements, but it can be scheduled to improve performance significantly. Loop unrolling is normally done early in the compilation process so that redundant computations can be exposed and eliminated by the optimizer.

In real programs, we do not usually know the upper bound on the loop. Suppose it is n , and we want to unroll the loop to make k copies of the body. Instead of a single unrolled loop, we generate a pair of consecutive loops. The first executes $(n \bmod k)$ times and has a body that is the original loop. The second is the unrolled body surrounded by an outer loop that iterates (n/k) times. (As we will see in [Chapter 4](#), this technique is similar to a technique called *strip mining*, used in compilers for vector processors.) For large values of n , most of the execution time will be spent in the unrolled loop body.

In the previous example, unrolling improves the performance of this loop by eliminating overhead instructions, although it increases code size substantially. How will the unrolled loop perform when it is scheduled for the pipeline described earlier?

Example Show the unrolled loop in the previous example after it has been scheduled for the pipeline with the latencies in [Figure 3.2](#).

Answer

```

Loop:  fld      f0,0(x1)
        fld      f6,-8(x1)
        fld      f0,-16(x1)
        fld      f14,-24(x1)
        fadd.d   f4,f0,f2
        fadd.d   f8,f6,f2
        fadd.d   f12,f0,f2
        fadd.d   f16,f14,f2
        fsd      f4,0(x1)
        fsd      f8,-8(x1)
        fsd      f12,16(x1)
        fsd      f16,8(x1)
        addi     x1,x1,-32
        bne      x1,x2,Loop
  
```

The execution time of the unrolled loop has dropped to a total of 14 clock cycles, or 3.5 clock cycles per element, compared with 8 cycles per element before any unrolling or scheduling and 6.5 cycles when unrolled but not scheduled.

The gain from scheduling on the unrolled loop is even larger than on the original loop. This increase arises because unrolling the loop exposes more computation that can be scheduled to minimize the stalls; the preceding code has no stalls. Scheduling the loop in this fashion necessitates realizing that the loads and stores are independent and can be interchanged.

Summary of the Loop Unrolling and Scheduling

Throughout this chapter and Appendix H, we will look at a variety of hardware and software techniques that allow us to take advantage of instruction-level parallelism to fully utilize the potential of the functional units in a processor. The key to most of these techniques is to know when and how the ordering among instructions may be changed. In our example, we made many such changes, which to us, as human beings, were obviously allowable. In practice, this process must be performed in a methodical fashion either by a compiler or by hardware. To obtain the final unrolled code, we had to make the following decisions and transformations:

- Determine that unrolling the loop would be useful by finding that the loop iterations were independent, except for the loop maintenance code.
- Use different registers to avoid unnecessary constraints that would be forced by using the same registers for different computations (e.g., name dependences).
- Eliminate the extra test and branch instructions and adjust the loop termination and iteration code.
- Determine that the loads and stores in the unrolled loop can be interchanged by observing that the loads and stores from different iterations are independent. This transformation requires analyzing the memory addresses and finding that they do not refer to the same address.
- Schedule the code, preserving any dependences needed to yield the same result as the original code.

The key requirement underlying all of these transformations is an understanding of how one instruction depends on another and how the instructions can be changed or reordered given the dependences.

Three different effects limit the gains from loop unrolling: (1) a decrease in the amount of overhead amortized with each unroll, (2) code size limitations, and (3) compiler limitations. Let's consider the question of loop overhead first. When we unrolled the loop four times, it generated sufficient parallelism among the instructions that the loop could be scheduled with no stall cycles. In fact, in 14 clock cycles, only 2 cycles were loop overhead: the `addi`, which maintains the index value, and the `bne`, which terminates the loop. If the loop is unrolled eight times, the overhead is reduced from 1/2 cycle per element to 1/4.

A second limit to unrolling is the resulting growth in code size. For larger loops, the code size growth may be a concern, particularly if it causes an increase in the instruction cache miss rate.

Another factor often more important than code size is the potential shortfall in registers that is created by aggressive unrolling and scheduling. This secondary effect that results from instruction scheduling in large code segments is called *register pressure*. It arises because scheduling code to increase ILP causes the number of live values to increase. After aggressive instruction scheduling, it may not be possible to allocate all the live values to registers. The transformed code, while theoretically faster, may lose some or all of its advantage because it leads to a shortage of registers. Without unrolling, aggressive scheduling is sufficiently limited by branches so that register pressure is rarely a problem. The combination of unrolling and aggressive scheduling can, however, cause this problem. The problem becomes especially challenging in multiple-issue processors that require the exposure of more independent instruction sequences whose execution can be overlapped. In general, the use of sophisticated high-level transformations, whose potential improvements are difficult to measure before detailed code generation, has led to significant increases in the complexity of modern compilers.

Loop unrolling is a simple but useful method for increasing the size of straight-line code fragments that can be scheduled effectively. This transformation is useful in a variety of processors, from simple pipelines like those we have examined so far to the multiple-issue superscalars and VLIWs explored later in this chapter.

3.3

Reducing Branch Costs With Advanced Branch Prediction

Because of the need to enforce control dependences through branch hazards and stalls, branches will hurt pipeline performance. Loop unrolling is one way to reduce the number of branch hazards; we can also reduce the performance losses of branches by predicting how they will behave. In [Appendix C](#), we examine simple branch predictors that rely either on compile-time information or on the observed dynamic behavior of a single branch in isolation. As the number of instructions in flight has increased with deeper pipelines and more issues per clock, the importance of more accurate branch prediction has grown. In this section, we examine techniques for improving dynamic prediction accuracy. This section makes extensive use of the simple 2-bit predictor covered in [Section C.2](#), and it is critical that the reader understand the operation of that predictor before proceeding.

Correlating Branch Predictors

The 2-bit predictor schemes in [Appendix C](#) use only the recent behavior of a single branch to predict the future behavior of that branch. It may be possible to improve the prediction accuracy if we also look at the recent behavior of *other* branches rather than just the branch we are trying to predict. Consider a small code fragment from the eqntott benchmark, a member of early SPEC benchmark suites that displayed particularly bad branch prediction behavior:

```

if (aa==2)
    aa=0;
if (bb==2)
    bb=0;
if (aa!=bb) {

```

Here is the RISC-V code that we would typically generate for this code fragment assuming that `aa` and `bb` are assigned to registers `x1` and `x2`:

```

        addi x3,x1,-2
        bnez x3,L1      //branch b1   (aa!=2)
        add  x1,x0,x0    //aa=0
L1:     addi x3,x2,-2
        bnez x3,L2      //branch b2   (bb!=2)
        add  x2,x0,x0    //bb=0
L2:     sub  x3,x1,x2     //x3=aa-bb
        beqz x3,L3      //branch b3   (aa==bb)

```

Let's label these branches `b1`, `b2`, and `b3`. The key observation is that the behavior of branch `b3` is correlated with the behavior of branches `b1` and `b2`. Clearly, if neither branches `b1` nor `b2` are taken (i.e., if the conditions both evaluate to true and `aa` and `bb` are both assigned 0), then `b3` will be taken, because `aa` and `bb` are clearly equal. A predictor that uses the behavior of only a single branch to predict the outcome of that branch can never capture this behavior.

Branch predictors that use the behavior of other branches to make a prediction are called *correlating predictors* or *two-level predictors*. Existing correlating predictors add information about the behavior of the most recent branches to decide how to predict a given branch. For example, a (1,2) predictor uses the behavior of the last branch to choose from among a pair of 2-bit branch predictors in predicting a particular branch. In the general case, an (m,n) predictor uses the behavior of the last m branches to choose from 2^m branch predictors, each of which is an n -bit predictor for a single branch. The attraction of this type of correlating branch predictor is that it can yield higher prediction rates than the 2-bit scheme and requires only a trivial amount of additional hardware.

The simplicity of the hardware comes from a simple observation: the global history of the most recent m branches can be recorded in an m -bit shift register, where each bit records whether the branch was taken or not taken. The branch-prediction buffer can then be indexed using a concatenation of the low-order bits from the branch address with the m -bit global history. For example, in a (2,2) buffer with 64 total entries, the 4 low-order address bits of the branch (word address) and the 2 global bits representing the behavior of the two most recently executed branches form a 6-bit index that can be used to index the 64 counters. By combining the local and global information by concatenation (or a simple hash function), we can index the predictor table with the result and get a prediction as fast as we could for the standard 2-bit predictor, as we will do very shortly.

How much better do the correlating branch predictors work when compared with the standard 2-bit scheme? To compare them fairly, we must compare predictors that use the same number of state bits. The number of bits in an (m,n) predictor is

$$2^m \times n \times \text{Number of prediction entries selected by the branch address}$$

A 2-bit predictor with no global history is simply a (0,2) predictor.

Example How many bits are in the (0,2) branch predictor with 4K entries? How many entries are in a (2,2) predictor with the same number of bits?

Answer The predictor with 4K entries has

$$2^0 \times 2 \times 4K = 8K \text{ bits}$$

How many branch-selected entries are in a (2,2) predictor that has a total of 8K bits in the prediction buffer? We know that

$$2^2 \times 2 \times \text{Number of prediction entries selected by the branch} = 8K$$

Therefore the number of prediction entries selected by the branch = 1K.

Figure 3.3 compares the misprediction rates of the earlier (0,2) predictor with 4K entries and a (2,2) predictor with 1K entries. As you can see, this correlating predictor not only outperforms a simple 2-bit predictor with the same total number of state bits, but it also often outperforms a 2-bit predictor with an unlimited number of entries.

Perhaps the best-known example of a correlating predictor is McFarling's gshare predictor. In gshare the index is formed by combining the address of the branch and the most recent conditional branch outcomes using an exclusive-OR, which essentially acts as a hash of the branch address and the branch history. The hashed result is used to index a prediction array of 2-bit counters, as shown in Figure 3.4. The gshare predictor works remarkably well for a simple predictor, and is often used as the baseline for comparison with more sophisticated predictors. Predictors that combine local branch information and global branch history are also called *alloyed predictors* or *hybrid predictors*.

Tournament Predictors: Adaptively Combining Local and Global Predictors

The primary motivation for correlating branch predictors came from the observation that the standard 2-bit predictor, using only local information, failed on some important branches. Adding global history could help remedy this situation. *Tournament predictors* take this insight to the next level, by using multiple predictors, usually a global predictor and a local predictor, and choosing between them

Figure 3.3 Comparison of 2-bit predictors. A noncorrelating predictor for 4096 bits is first, followed by a noncorrelating 2-bit predictor with unlimited entries and a 2-bit predictor with 2 bits of global history and a total of 1024 entries. Although these data are for an older version of SPEC, data for more recent SPEC benchmarks would show similar differences in accuracy.

with a selector, as shown in [Figure 3.5](#). A *global predictor* uses the most recent branch history to index the predictor, while a *local predictor* uses the address of the branch as the index. Tournament predictors are another form of hybrid or alloyed predictors.

Tournament predictors can achieve better accuracy at medium sizes (8K–32K bits) and also effectively use very large numbers of prediction bits. Existing tournament predictors use a 2-bit saturating counter per branch to choose among two different predictors based on which predictor (local, global, or even some time-varying mix) was most effective in recent predictions. As in a simple 2-bit predictor, the saturating counter requires two mispredictions before changing the identity of the preferred predictor.

The advantage of a tournament predictor is its ability to select the right predictor for a particular branch, which is particularly crucial for the integer benchmarks.

Figure 3.4 A gshare predictor with 1024 entries, each being a standard 2-bit predictor.

Figure 3.5 A tournament predictor using the branch address to index a set of 2-bit selection counters, which choose between a local and a global predictor. In this case, the index to the selector table is the current branch address. The two tables are also 2-bit predictors that are indexed by the global history and branch address, respectively. The selector acts like a 2-bit predictor, changing the preferred predictor for a branch address when two mispredicts occur in a row. The number of bits of the branch address used to index the selector table and the local predictor table is equal to the length of the global branch history used to index the global prediction table. Note that misprediction is a bit tricky because we need to change both the selector table and either the global or local predictor.

A typical tournament predictor will select the global predictor almost 40% of the time for the SPEC integer benchmarks and less than 15% of the time for the SPEC FP benchmarks. In addition to the Alpha processors that pioneered tournament predictors, several AMD processors have used tournament-style predictors.

Figure 3.6 looks at the performance of three different predictors (a local 2-bit predictor, a correlating predictor, and a tournament predictor) for different numbers of bits using SPEC89 as the benchmark. The local predictor reaches its limit first. The correlating predictor shows a significant improvement, and the tournament predictor generates a slightly better performance. For more recent versions of the SPEC, the results would be similar, but the asymptotic behavior would not be reached until slightly larger predictor sizes.

The local predictor consists of a two-level predictor. The top level is a local history table consisting of 1024 10-bit entries; each 10-bit entry corresponds to the most recent 10 branch outcomes for the entry. That is, if the branch is taken 10 or more times in a row, the entry in the local history table will be all 1s. If the branch is alternately taken and untaken, the history entry consists of alternating 0s and 1s. This 10-bit history allows patterns of up to 10 branches to be discovered and predicted. The selected entry from the local history table is used to index a table of 1K entries consisting of 3-bit saturating counters, which provide the local prediction. This combination, which uses a total of 29K bits, leads to high accuracy in

Figure 3.6 The misprediction rate for three different predictors on SPEC89 versus the size of the predictor in kilobits. The predictors are a local 2-bit predictor, a correlating predictor that is optimally structured in its use of global and local information at each point in the graph, and a tournament predictor. Although these data are for an older version of SPEC, data for more recent SPEC benchmarks show similar behavior, perhaps converging to the asymptotic limit at slightly larger predictor sizes.

branch prediction while requiring fewer bits than a single level table with the same prediction accuracy.

Tagged Hybrid Predictors

The best performing branch prediction schemes as of 2017 involve combining multiple predictors that track whether a prediction is likely to be associated with the current branch. One important class of predictors is loosely based on an algorithm for statistical compression called PPM (Prediction by Partial Matching). PPM (see Jiménez and Lin, 2001), like a branch prediction algorithm, attempts to predict future behavior based on history. This class of branch predictors, which we call *tagged hybrid predictors* (see Seznec and Michaud, 2006), employs a series of global predictors indexed with different length histories.

For example, as shown in Figure 3.7, a five-component tagged hybrid predictor has five prediction tables: $P(0)$, $P(1)$, \dots , $P(4)$, where $P(i)$ is accessed using a hash of

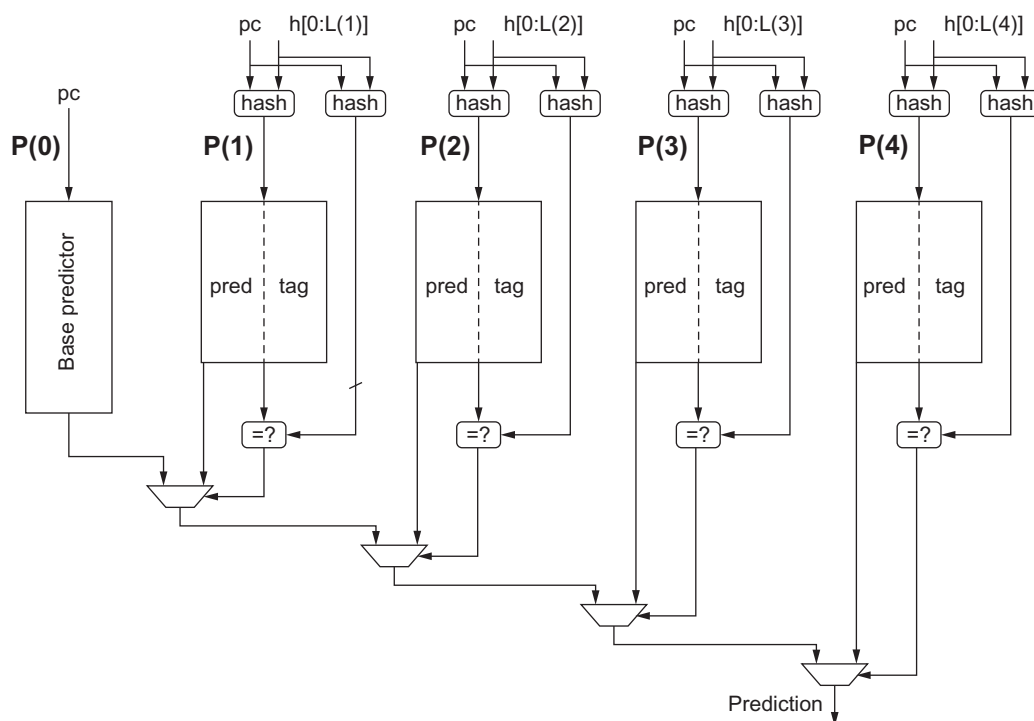

Figure 3.7 A five-component tagged hybrid predictor has five separate prediction tables, indexed by a hash of the branch address and a segment of recent branch history of length 0–4 labeled “h” in this figure. The hash can be as simple as an exclusive-OR, as in gshare. Each predictor is a 2-bit (or possibly 3-bit) predictor. The tags are typically 4–8 bits. The chosen prediction is the one with the longest history where the tags also match.

the PC and the history of the most recent i branches (kept in a shift register, h , just as in *gshare*). The use of multiple history lengths to index separate predictors is the first critical difference. The second critical difference is the use of tags in tables $P(1)$ through $P(4)$. The tags can be short because 100% matches are not required: a small tag of 4–8 bits appears to gain most of the advantage. A prediction from $P(1)$, . . . $P(4)$ is used only if the tags match the hash of the branch address and global branch history. Each of the predictors in $P(0..n)$ can be a standard 2-bit predictor. In practice a 3-bit counter, which requires three mispredictions to change a prediction, gives slightly better results than a 2-bit counter.

The prediction for a given branch is the predictor with the longest branch history that also has matching tags. $P(0)$ always matches because it uses no tags and becomes the default prediction if none of $P(1)$ through $P(n)$ match. The tagged hybrid version of this predictor also includes a 2-bit use field in each of the history-indexed predictors. The use field indicates whether a prediction was recently used and therefore likely to be more accurate; the use field can be periodically reset in all entries so that old predictions are cleared. Many more details are involved in implementing this style of predictor, especially how to handle mispredictions. The search space for the optimal predictor is also very large because the number of predictors, the exact history used for indexing, and the size of each predictor are all variable.

Tagged hybrid predictors (sometimes called TAGE—TAGged GEometric—predictors) and the earlier PPM-based predictors have been the winners in recent annual international branch-prediction competitions. Such predictors outperform *gshare* and the tournament predictors with modest amounts of memory (32–64 KiB), and in addition, this class of predictors seems able to effectively use larger prediction caches to deliver improved prediction accuracy.

Another issue for larger predictors is how to initialize the predictor. It could be initialized randomly, in which case, it will take a fair amount of execution time to fill the predictor with useful predictions. Some predictors (including many recent predictors) include a valid bit, indicating whether an entry in the predictor has been set or is in the “unused state.” In the latter case, rather than use a random prediction, we could use some method to initialize that prediction entry. For example, some instruction sets contain a bit that indicates whether an associated branch is expected to be taken or not. In the days before dynamic branch prediction, such hint bits *were* the prediction; in recent processors, that hint bit can be used to set the initial prediction. We could also set the initial prediction on the basis of the branch direction: forward going branches are initialized as not taken, while backward going branches, which are likely to be loop branches, are initialized as taken. For programs with shorter running times and processors with larger predictors, this initial setting can have a measurable impact on prediction performance.

Figure 3.8 shows that a hybrid tagged predictor significantly outperforms *gshare*, especially for the less predictable programs like SPECint and server applications. In this figure, performance is measured as mispredicts per thousand instructions; assuming a branch frequency of 20%–25%, *gshare* has a mispredict rate (per branch) of 2.7%–3.4% for the multimedia benchmarks, while the tagged

Figure 3.8 A comparison of the misprediction rate (measured as mispredicts per 1000 instructions executed) for tagged hybrid versus gshare. Both predictors use the same total number of bits, although tagged hybrid uses some of that storage for tags, while gshare contains no tags. The benchmarks consist of traces from SPECfp and SPECint, a series of multimedia and server benchmarks. The latter two behave more like SPECint.

hybrid predictor has a misprediction rate of 1.8%–2.2%, or roughly one-third fewer mispredicts. Compared to gshare, tagged hybrid predictors are more complex to implement and are probably slightly slower because of the need to check multiple tags and choose a prediction result. Nonetheless, for deeply pipelined processors with large penalties for branch misprediction, the increased accuracy outweighs those disadvantages. Thus many designers of higher-end processors have opted to include tagged hybrid predictors in their newest implementations.

The Evolution of the Intel Core i7 Branch Predictor

As mentioned in the previous chapter, there were six generations of Intel Core i7 processors between 2008 (Core i7 920 using the Nehalem microarchitecture) and 2016 (Core i7 6700 using the Skylake microarchitecture). Because of the combination of deep pipelining and multiple issues per clock, the i7 has many instructions in-flight at once (up to 256, and typically at least 30). This makes branch prediction critical, and it has been an area where Intel has been making constant improvements. Perhaps because of the performance-critical nature of the branch predictor, Intel has tended to keep the details of its branch predictors highly secret.

Even for older processors such as the Core i7 920 introduced in 2008, they have released only limited amounts of information. In this section, we briefly describe what is known and compare the performance of predictors of the Core i7 920 with those in the latest Core i7 6700.

The Core i7 920 used a two-level predictor that has a smaller first-level predictor, designed to meet the cycle constraints of predicting a branch every clock cycle, and a larger second-level predictor as a backup. Each predictor combines three different predictors: (1) the simple 2-bit predictor, which is introduced in [Appendix C](#) (and used in the preceding tournament predictor); (2) a global history predictor, like those we just saw; and (3) a loop exit predictor. The loop exit predictor uses a counter to predict the exact number of taken branches (which is the number of loop iterations) for a branch that is detected as a loop branch. For each branch, the best prediction is chosen from among the three predictors by tracking the accuracy of each prediction, like a tournament predictor. In addition to this multilevel main predictor, a separate unit predicts target addresses for indirect branches, and a stack to predict return addresses is also used.

Although even less is known about the predictors in the newest i7 processors, there is good reason to believe that Intel is employing a tagged hybrid predictor. One advantage of such a predictor is that it combines the functions of all three second-level predictors in the earlier i7. The tagged hybrid predictor with different history lengths subsumes the loop exit predictor as well as the local and global history predictor. A separate return address predictor is still employed.

As in other cases, speculation causes some challenges in evaluating the predictor because a mispredicted branch can easily lead to another branch being fetched and mispredicted. To keep things simple, we look at the number of mispredictions as a percentage of the number of successfully completed branches (those that were not the result of misspeculation). [Figure 3.9](#) shows these data for SPEC-PUint2006 benchmarks. These benchmarks are considerably larger than SPEC89 or SPEC2000, with the result being that the misprediction rates are higher than those in [Figure 3.6](#) even with a more powerful combination of predictors. Because branch misprediction leads to ineffective speculation, it contributes to the wasted work, as we will see later in this chapter.

3.4

Overcoming Data Hazards With Dynamic Scheduling

A simple statically scheduled pipeline fetches an instruction and issues it, unless there is a data dependence between an instruction already in the pipeline and the fetched instruction that cannot be hidden with bypassing or forwarding. (Forwarding logic reduces the effective pipeline latency so that the certain dependences do not result in hazards.) If there is a data dependence that cannot be hidden, then the hazard detection hardware stalls the pipeline starting with the instruction that uses the result. No new instructions are fetched or issued until the dependence is cleared.

In this section, we explore *dynamic scheduling*, a technique by which the hardware reorders the instruction execution to reduce the stalls while maintaining data

Figure 3.9 The misprediction rate for the integer SPEC CPU2006 benchmarks on the Intel Core i7 920 and 6700. The misprediction rate is computed as the ratio of completed branches that are mispredicted versus all completed branches. This could understate the misprediction rate somewhat because if a branch is mispredicted and led to another mispredicted branch (which should not have been executed), it will be counted as only one misprediction. On average, the i7 920 mispredicts branches 1.3 times as often as the i7 6700.

flow and exception behavior. Dynamic scheduling offers several advantages. First, it allows code that was compiled with one pipeline in mind to run efficiently on a different pipeline, eliminating the need to have multiple binaries and recompile for a different microarchitecture. In today's computing environment, where much of the software is from third parties and distributed in binary form, this advantage is significant. Second, it enables handling some cases when dependences are unknown at compile time; for example, they may involve a memory reference or a data-dependent branch, or they may result from a modern programming environment that uses dynamic linking or dispatching. Third, and perhaps most importantly, it allows the processor to tolerate unpredictable delays, such as cache misses, by executing other code while waiting for the miss to resolve. In [Section 3.6](#), we explore hardware speculation, a technique with additional performance advantages, which builds on dynamic scheduling. As we will see, the advantages of dynamic scheduling are gained at the cost of a significant increase in hardware complexity.

Although a dynamically scheduled processor cannot change the data flow, it tries to avoid stalling when dependences are present. In contrast, static pipeline scheduling by the compiler (covered in [Section 3.2](#)) tries to minimize stalls by separating dependent instructions so that they will not lead to hazards. Of course,

compiler pipeline scheduling can also be used in code destined to run on a processor with a dynamically scheduled pipeline.

Dynamic Scheduling: The Idea

A major limitation of simple pipelining techniques is that they use in-order instruction issue and execution: instructions are issued in program order, and if an instruction is stalled in the pipeline, no later instructions can proceed. Thus, if there is a dependence between two closely spaced instructions in the pipeline, it will lead to a hazard, and a stall will result. If there are multiple functional units, these units could lie idle. If instruction j depends on a long-running instruction i , currently in execution in the pipeline, then all instructions after j must be stalled until i is finished and j can execute. For example, consider this code:

```
fdiv.d  f0,f2,f4
fadd.d  f10,f0,f8
fsub.d  f12,f8,f14
```

The `fsub.d` instruction cannot execute because the dependence of `fadd.d` on `fdiv.d` causes the pipeline to stall; yet, `fsub.d` is not data-dependent on anything in the pipeline. This hazard creates a performance limitation that can be eliminated by not requiring instructions to execute in program order.

In the classic five-stage pipeline, both structural and data hazards could be checked during instruction decode (ID): when an instruction could execute without hazards, it was issued from ID, with the recognition that all data hazards had been resolved.

To allow us to begin executing the `fsub.d` in the preceding example, we must separate the issue process into two parts: checking for any structural hazards and waiting for the absence of a data hazard. Thus we still use in-order instruction issue (i.e., instructions issued in program order), but we want an instruction to begin execution as soon as its data operands are available. Such a pipeline does *out-of-order execution*, which implies *out-of-order completion*.

Out-of-order execution introduces the possibility of WAR and WAW hazards, which do not exist in the five-stage integer pipeline and its logical extension to an in-order floating-point pipeline. Consider the following RISC-V floating-point code sequence:

```
fdiv.d  f0,f2,f4
fmul.d  f6,f0,f8
fadd.d  f0,f10,f14
```

There is an antidependence between the `fmul.d` and the `fadd.d` (for the register `f0`), and if the pipeline executes the `fadd.d` before the `fmul.d` (which is waiting for the `fdiv.d`), it will violate the antidependence, yielding a WAR hazard. Likewise, to avoid violating output dependences, such as the write of `f0` by `fadd.d` before `fdiv.d` completes, WAW hazards must be handled. As we will see, both these hazards are avoided by the use of register renaming.

Out-of-order completion also creates major complications in handling exceptions. Dynamic scheduling with out-of-order completion must preserve exception behavior in the sense that *exactly* those exceptions that would arise if the program were executed in strict program order *actually* do arise. Dynamically scheduled processors preserve exception behavior by delaying the notification of an associated exception until the processor knows that the instruction should be the next one completed.

Although exception behavior must be preserved, dynamically scheduled processors could generate *imprecise* exceptions. An exception is *imprecise* if the processor state when an exception is raised does not look exactly as if the instructions were executed sequentially in strict program order. Imprecise exceptions can occur because of two possibilities:

1. The pipeline may have *already completed* instructions that are *later* in program order than the instruction causing the exception.
2. The pipeline may have *not yet completed* some instructions that are *earlier* in program order than the instruction causing the exception.

Imprecise exceptions make it difficult to restart execution after an exception. Rather than address these problems in this section, we will discuss a solution that provides precise exceptions in the context of a processor with speculation in [Section 3.6](#). For floating-point exceptions, other solutions have been used, as discussed in Appendix J.

To allow out-of-order execution, we essentially split the ID pipe stage of our simple five-stage pipeline into two stages:

1. *Issue*—Decode instructions, check for structural hazards.
2. *Read operands*—Wait until no data hazards, then read operands.

An instruction fetch stage precedes the issue stage and may fetch either to an instruction register or into a queue of pending instructions; instructions are then issued from the register or queue. The execution stage follows the read operands stage, just as in the five-stage pipeline. Execution may take multiple cycles, depending on the operation.

We distinguish when an instruction *begins execution* and when it *completes execution*; between the two times, the instruction is *in execution*. Our pipeline allows multiple instructions to be in execution at the same time; without this capability, a major advantage of dynamic scheduling is lost. Having multiple instructions in execution at once requires multiple functional units, pipelined functional units, or both. Because these two capabilities—pipelined functional units and multiple functional units—are essentially equivalent for the purposes of pipeline control, we will assume the processor has multiple functional units.

In a dynamically scheduled pipeline, all instructions pass through the issue stage in order (in-order issue); however, they can be stalled or can bypass each

other in the second stage (read operands) and thus enter execution out of order. *Scoreboarding* is a technique for allowing instructions to execute out of order when there are sufficient resources and no data dependences; it is named after the CDC 6600 scoreboard, which developed this capability. Here we focus on a more sophisticated technique, called *Tomasulo's algorithm*. The primary difference is that Tomasulo's algorithm handles antidependences and output dependences by effectively renaming the registers dynamically. Additionally, Tomasulo's algorithm can be extended to handle *speculation*, a technique to reduce the effect of control dependences by predicting the outcome of a branch, executing instructions at the predicted destination address, and taking corrective actions when the prediction was wrong. While the use of scoreboarding is probably sufficient to support simpler processors, more sophisticated, higher performance processors make use of speculation.

Dynamic Scheduling Using Tomasulo's Approach

The IBM 360/91 floating-point unit used a sophisticated scheme to allow out-of-order execution. This scheme, invented by Robert Tomasulo, tracks when operands for instructions are available to minimize RAW hazards and introduces register renaming in hardware to minimize WAW and WAR hazards. Although there are many variations of this scheme in recent processors, they all rely on two key principles: dynamically determining when an instruction is ready to execute and renaming registers to avoid unnecessary hazards.

IBM's goal was to achieve high floating-point performance from an instruction set and from compilers designed for the entire 360 computer family, rather than from specialized compilers for the high-end processors. The 360 architecture had only four double-precision floating-point registers, which limited the effectiveness of compiler scheduling; this fact was another motivation for the Tomasulo approach. In addition, the IBM 360/91 had long memory accesses and long floating-point delays, which Tomasulo's algorithm was designed to overcome. At the end of the section, we will see that Tomasulo's algorithm can also support the overlapped execution of multiple iterations of a loop.

We explain the algorithm, which focuses on the floating-point unit and load-store unit, in the context of the RISC-V instruction set. The primary difference between RISC-V and the 360 is the presence of register-memory instructions in the latter architecture. Because Tomasulo's algorithm uses a load functional unit, no significant changes are needed to add register-memory addressing modes. The IBM 360/91 also had pipelined functional units, rather than multiple functional units, but we describe the algorithm as if there were multiple functional units. It is a simple conceptual extension to also pipeline those functional units.

RAW hazards are avoided by executing an instruction only when its operands are available, which is exactly what the simpler scoreboarding approach provides. WAR and WAW hazards, which arise from name dependences, are eliminated by register renaming. *Register renaming* eliminates these hazards by renaming all

destination registers, including those with a pending read or write for an earlier instruction, so that the out-of-order write does not affect any instructions that depend on an earlier value of an operand. The compiler could typically implement such renaming, if there were enough registers available in the ISA. The original 360/91 had only four floating-point registers, and Tomasulo's algorithm was created to overcome this shortage. Whereas modern processors have 32–64 floating-point and integer registers, the number of renaming registers available in recent implementations is in the hundreds.

To better understand how register renaming eliminates WAR and WAW hazards, consider the following example code sequence that includes potential WAR and WAW hazards:

```
fdiv.d  f0,f2,f4
fadd.d  f6,f0,f8
fsd     f6,0(x1)
fsub.d  f8,f10,f14
fmul.d  f6,f10,f8
```

There are two antidependences: between the `fadd.d` and the `fsub.d` and between the `fsd` and the `fmul.d`. There is also an output dependence between the `fadd.d` and the `fmul.d`, leading to three possible hazards: WAR hazards on the use of `f8` by `fadd.d` and its use by the `fsub.d`, as well as a WAW hazard because the `fadd.d` may finish later than the `fmul.d`. There are also three true data dependences: between the `fdiv.d` and the `fadd.d`, between the `fsub.d` and the `fmul.d`, and between the `fadd.d` and the `fsd`.

These three name dependences can all be eliminated by register renaming. For simplicity, assume the existence of two temporary registers, `S` and `T`. Using `S` and `T`, the sequence can be rewritten without any dependences as

```
fdiv.d  f0,f2,f4
fadd.d  S,f0,f8
fsd     S,0(x1)
fsub.d  T,f10,f14
fmul.d  f6,f10,T
```

In addition, any subsequent uses of `f8` must be replaced by the register `T`. In this example, the renaming process can be done statically by the compiler. Finding any uses of `f8` that are later in the code requires either sophisticated compiler analysis or hardware support because there may be intervening branches between the preceding code segment and a later use of `f8`. As we will see, Tomasulo's algorithm can handle renaming across branches.

In Tomasulo's scheme, register renaming is provided by *reservation stations*, which buffer the operands of instructions waiting to issue and are associated with the functional units. The basic idea is that a reservation station fetches and buffers an operand as soon as it is available, eliminating the need to get the operand from a register. In addition, pending instructions designate the reservation station that will provide their input. Finally, when successive writes to a register overlap in

execution, only the last one is actually used to update the register. As instructions are issued, the register specifiers for pending operands are renamed to the names of the reservation station, which provides register renaming.

Because there can be more reservation stations than real registers, the technique can even eliminate hazards arising from name dependences that could not be eliminated by a compiler. As we explore the components of Tomasulo's scheme, we will return to the topic of register renaming and see exactly how the renaming occurs and how it eliminates WAR and WAW hazards.

The use of reservation stations, rather than a centralized register file, leads to two other important properties. First, hazard detection and execution control are distributed: the information held in the reservation stations at each functional unit determines when an instruction can begin execution at that unit. Second, results are passed directly to functional units from the reservation stations where they are buffered, rather than going through the registers. This bypassing is done with a common result bus that allows all units waiting for an operand to be loaded simultaneously (on the 360/91, this is called the *common data bus*, or CDB). In pipelines that issue multiple instructions per clock and also have multiple execution units, more than one result bus will be needed.

Figure 3.10 shows the basic structure of a Tomasulo-based processor, including both the floating-point unit and the load/store unit; none of the execution control tables is shown. Each reservation station holds an instruction that has been issued and is awaiting execution at a functional unit. If the operand values for that instruction have been computed, they are also stored in that entry; otherwise, the reservation station entry keeps the names of the reservation stations that will provide the operand values.

The load buffers and store buffers hold data or addresses coming from and going to memory and behave almost exactly like reservation stations, so we distinguish them only when necessary. The floating-point registers are connected by a pair of buses to the functional units and by a single bus to the store buffers. All results from the functional units and from memory are sent on the common data bus, which goes everywhere except to the load buffer. All reservation stations have tag fields, employed by the pipeline control.

Before we describe the details of the reservation stations and the algorithm, let's look at the steps an instruction goes through. There are only three steps, although each one can now take an arbitrary number of clock cycles:

1. *Issue*—Get the next instruction from the head of the instruction queue, which is maintained in FIFO order to ensure the maintenance of correct data flow. If there is a matching reservation station that is empty, issue the instruction to the station with the operand values, if they are currently in the registers. If there is not an empty reservation station, then there is a structural hazard, and the instruction issue stalls until a station or buffer is freed. If the operands are not in the registers, keep track of the functional units that will produce the operands. This step renames registers, eliminating WAR and WAW hazards. (This stage is sometimes called *dispatch* in a dynamically scheduled processor.)

Figure 3.10 The basic structure of a RISC-V floating-point unit using Tomasulo's algorithm. Instructions are sent from the instruction unit into the instruction queue from which they are issued in first-in, first-out (FIFO) order. The reservation stations include the operation and the actual operands, as well as information used for detecting and resolving hazards. Load buffers have three functions: (1) hold the components of the effective address until it is computed, (2) track outstanding loads that are waiting on the memory, and (3) hold the results of completed loads that are waiting for the CDB. Similarly, store buffers have three functions: (1) hold the components of the effective address until it is computed, (2) hold the destination memory addresses of outstanding stores that are waiting for the data value to store, and (3) hold the address and value to store until the memory unit is available. All results from either the FP units or the load unit are put on the CDB, which goes to the FP register file as well as to the reservation stations and store buffers. The FP adders implement addition and subtraction, and the FP multipliers do multiplication and division.

2. *Execute*—If one or more of the operands is not yet available, monitor the common data bus while waiting for it to be computed. When an operand becomes available, it is placed into any reservation station awaiting it. When all the operands are available, the operation can be executed at the corresponding functional unit. By delaying instruction execution until the operands are available, RAW hazards are avoided. (Some dynamically scheduled processors call this step “issue,” but we use the name “execute,” which was used in the first dynamically scheduled processor, the CDC 6600.)

Notice that several instructions could become ready in the same clock cycle for the same functional unit. Although independent functional units could begin execution in the same clock cycle for different instructions, if more than one instruction is ready for a single functional unit, the unit will have to choose among them. For the floating-point reservation stations, this choice may be made arbitrarily; loads and stores, however, present an additional complication.

Loads and stores require a two-step execution process. The first step computes the effective address when the base register is available, and the effective address is then placed in the load or store buffer. Loads in the load buffer execute as soon as the memory unit is available. Stores in the store buffer wait for the value to be stored before being sent to the memory unit. Loads and stores are maintained in program order through the effective address calculation, which will help to prevent hazards through memory.

To preserve exception behavior, no instruction is allowed to initiate execution until a branch that precedes the instruction in program order has completed. This restriction guarantees that an instruction that causes an exception during execution really would have been executed. In a processor using branch prediction (as all dynamically scheduled processors do), this means that the processor must know that the branch prediction was correct before allowing an instruction after the branch to begin execution. If the processor records the occurrence of the exception, but does not actually raise it, an instruction can start execution but not stall until it enters Write Result.

Speculation provides a more flexible and more complete method to handle exceptions, so we will delay making this enhancement and show how speculation handles this problem later.

3. *Write result*—When the result is available, write it on the CDB and from there into the registers and into any reservation stations (including store buffers) waiting for this result. Stores are buffered in the store buffer until both the value to be stored and the store address are available; then the result is written as soon as the memory unit is free.

The data structures that detect and eliminate hazards are attached to the reservation stations, to the register file, and to the load and store buffers with slightly different information attached to different objects. These tags are essentially names for an extended set of virtual registers used for renaming. In our example, the tag field is a 4-bit quantity that denotes one of the five reservation stations or one of the five load buffers. This combination produces the equivalent of 10 registers (5 reservation stations + 5 load buffers) that can be designated as result registers (as opposed to the four double-precision registers that the 360 architecture contains). In a processor with more real registers, we want renaming to provide an even larger set of virtual registers, often numbering in the hundreds. The tag field describes which reservation station contains the instruction that will produce a result needed as a source operand.

Once an instruction has issued and is waiting for a source operand, it refers to the operand by the reservation station number where the instruction that will write

the register has been assigned. Unused values, such as zero, indicate that the operand is already available in the registers. Because there are more reservation stations than actual register numbers, WAW and WAR hazards are eliminated by renaming results using reservation station numbers. Although in Tomasulo's scheme the reservation stations are used as the extended virtual registers, other approaches could use a register set with additional registers or a structure like the reorder buffer, which we will see in [Section 3.6](#).

In Tomasulo's scheme, as well as the subsequent methods we look at for supporting speculation, results are broadcast on a bus (the CDB), which is monitored by the reservation stations. The combination of the common result bus and the retrieval of results from the bus by the reservation stations implements the forwarding and bypassing mechanisms used in a statically scheduled pipeline. In doing so, however, a dynamically scheduled scheme, such as Tomasulo's algorithm, introduces one cycle of latency between source and result because the matching of a result and its use cannot be done until the end of the Write Result stage, as opposed to the end of the Execute stage for a simpler pipeline. Thus, in a dynamically scheduled pipeline, the effective latency between a producing instruction and a consuming instruction is at least one cycle longer than the latency of the functional unit producing the result.

It is important to remember that the tags in the Tomasulo scheme refer to the buffer or unit that will produce a result; the register names are discarded when an instruction issues to a reservation station. (This is a key difference between Tomasulo's scheme and scoreboarding: in scoreboarding, operands stay in the registers and are read only after the producing instruction completes and the consuming instruction is ready to execute.)

Each reservation station has seven fields:

- Op—The operation to perform on source operands S1 and S2.
- Qj, Qk—The reservation stations that will produce the corresponding source operand; a value of zero indicates that the source operand is already available in Vj or Vk, or is unnecessary.
- Vj, Vk—The value of the source operands. Note that only one of the V fields or the Q field is valid for each operand. For loads, the Vk field is used to hold the offset field.
- A—Used to hold information for the memory address calculation for a load or store. Initially, the immediate field of the instruction is stored here; after the address calculation, the effective address is stored here.
- Busy—Indicates that this reservation station and its accompanying functional unit are occupied.

The register file has a field, Qi:

- Qi—The number of the reservation station that contains the operation whose result should be stored into this register. If the value of Qi is blank (or 0), no

currently active instruction is computing a result destined for this register, meaning that the value is simply the register contents.

The load and store buffers each have a field, A, which holds the result of the effective address once the first step of execution has been completed.

In the next section, we will first consider some examples that show how these mechanisms work and then examine the detailed algorithm.

3.5

Dynamic Scheduling: Examples and the Algorithm

Before we examine Tomasulo's algorithm in detail, let's consider a few examples that will help illustrate how the algorithm works.

Example Show what the information tables look like for the following code sequence when only the first load has completed and written its result:

```

1. fld      f6,32(x2)
2. fld      f2,44(x3)
3. fmul.d   f0,f2,f4
4. fsub.d   f8,f2,f6
5. fdiv.d   f0,f0,f6
6. fadd.d   f6,f8,f2

```

Answer Figure 3.11 shows the result in three tables. The numbers appended to the names Add, Mult, and Load stand for the tag for that reservation station—Add1 is the tag for the result from the first add unit. In addition, we have included an instruction status table. This table is included only to help you understand the algorithm; it is *not* actually a part of the hardware. Instead, the reservation station keeps the state of each operation that has issued.

Tomasulo's scheme offers two major advantages over earlier and simpler schemes: (1) the distribution of the hazard detection logic, and (2) the elimination of stalls for WAW and WAR hazards.

The first advantage arises from the distributed reservation stations and the use of the CDB. If multiple instructions are waiting on a single result, and each instruction already has its other operand, then the instructions can be released simultaneously by the broadcast of the result on the CDB. If a centralized register file were used, the units would have to read their results from the registers when register buses were available.

The second advantage, the elimination of WAW and WAR hazards, is accomplished by renaming registers using the reservation stations and by the process of storing operands into the reservation station as soon as they are available.

For example, the code sequence in Figure 3.11 issues both the `fdiv.d` and the `fadd.d`, even though there is a WAR hazard involving `f6`. The hazard is

eliminated in one of two ways. First, if the instruction providing the value for the `fdiv.d` has completed, then `Vk` will store the result, allowing `fdiv.d` to execute independent of the `fadd.d` (this is the case shown). On the other hand, if the `fld` hasn't completed, then `Qk` will point to the `Load1` reservation station, and the `fdiv.d` instruction will be independent of the `fadd.d`. Thus, in either case, the `fadd.d` can issue and begin executing. Any uses of the result of the `fdiv.d` will point to the reservation station, allowing the `fadd.d` to complete and store its value into the registers without affecting the `fdiv.d`.

Instruction		Instruction status		
		Issue	Execute	Write result
<code>fld</code>	<code>f6,32(x2)</code>	✓	✓	✓
<code>fld</code>	<code>f2,44(x3)</code>	✓	✓	
<code>fmul.d</code>	<code>f0,f2,f4</code>	✓		
<code>fsub.d</code>	<code>f8,f2,f6</code>	✓		
<code>fdiv.d</code>	<code>f0,f0,f6</code>	✓		
<code>fadd.d</code>	<code>f6,f8,f2</code>	✓		

Reservation stations							
Name	Busy	Op	Vj	Vk	Qj	Qk	A
Load1	No						
Load2	Yes	Load					44 + Regs[x3]
Add1	Yes	SUB		Mem[32 + Regs[x2]]	Load2		
Add2	Yes	ADD			Add1	Load2	
Add3	No						
Mult1	Yes	MUL		Regs[f4]	Load2		
Mult2	Yes	DIV		Mem[32 + Regs[x2]]	Mult1		

Register status									
Field	f0	f2	f4	f6	f8	f10	f12	...	f30
Qi	Mult1	Load2		Add2	Add1	Mult2			

Figure 3.11 Reservation stations and register tags shown when all of the instructions have issued but only the first load instruction has completed and written its result to the CDB. The second load has completed effective address calculation but is waiting on the memory unit. We use the array `Regs[]` to refer to the register file and the array `Mem[]` to refer to the memory. Remember that an operand is specified by either a `Q` field or a `V` field at any time. Notice that the `fadd.d` instruction, which has a WAR hazard at the WB stage, has issued and could complete before the `fdiv.d` initiates.

We'll see an example of the elimination of a WAW hazard shortly. But let's first look at how our earlier example continues execution. In this example, and the ones that follow in this chapter, assume the following latencies: load is 1 clock cycle, add is 2 clock cycles, multiply is 6 clock cycles, and divide is 12 clock cycles.

Example Using the same code segment as in the previous example (page 201), show what the status tables look like when the `fmul.d` is ready to write its result.

Answer The result is shown in the three tables in Figure 3.12. Notice that `fadd.d` has completed because the operands of `fdiv.d` were copied, thereby overcoming the WAR hazard. Notice that even if the load of `f6` was `fdiv.d`, the add into `f6` could be executed without triggering a WAW hazard.

Instruction		Instruction status		
		Issue	Execute	Write result
<code>fld</code>	<code>f6, 32(x2)</code>	✓	✓	✓
<code>fld</code>	<code>f2, 44(x3)</code>	✓	✓	✓
<code>fmul.d</code>	<code>f0, f2, f4</code>	✓	✓	
<code>fsub.d</code>	<code>f8, f2, f6</code>	✓	✓	✓

Figure 3.12 Multiply and divide are the only instructions not finished.

Tomasulo's Algorithm: The Details

Figure 3.13 specifies the checks and steps that each instruction must go through. As mentioned earlier, loads and stores go through a functional unit for effective address computation before proceeding to independent load or store buffers. Loads take a second execution step to access memory and then go to Write Result to send the value from memory to the register file and/or any waiting reservation stations. Stores complete their execution in the Write Result stage, which writes the result to memory. Notice that all writes occur in Write Result, whether the destination is a register or memory. This restriction simplifies Tomasulo's algorithm and is critical to its extension with speculation in Section 3.6.

Tomasulo's Algorithm: A Loop-Based Example

To understand the full power of eliminating WAW and WAR hazards through dynamic renaming of registers, we must look at a loop. Consider the following simple sequence for multiplying the elements of an array by a scalar in f2:

```

Loop: fld      f0,0(x1)
      fmul.d   f4,f0,f2
      fsd      f4,0(x1)
      addi     x1,x1,-8
      bne      x1,x2,Loop // branches if x1≠x2

```

If we predict that branches are taken, using reservation stations will allow multiple executions of this loop to proceed at once. This advantage is gained without changing the code—in effect, the loop is unrolled dynamically by the hardware using the reservation stations obtained by renaming to act as additional registers.

Let's assume we have issued all the instructions in two successive iterations of the loop, but none of the floating-point load/stores or operations have completed. Figure 3.14 shows reservation stations, register status tables, and load and store buffers at this point. (The integer ALU operation is ignored, and it is assumed the branch was predicted as taken.) Once the system reaches this state, two copies of the loop could be sustained with a CPI close to 1.0, provided the multiplies could complete in four clock cycles. With a latency of six cycles, additional iterations will need to be processed before the steady state can be reached. This requires more reservation stations to hold instructions that are in execution. As we will see later in this chapter, when extended with multiple issue instructions, Tomasulo's approach can sustain more than one instruction per clock.

A load and a store can be done safely out of order, provided they access different addresses. If a load and a store access the same address, one of two things happens:

Instruction state	Wait until	Action or bookkeeping
Issue FP operation	Station r empty	<pre> if (RegisterStat[rs].Qi≠0) {RS[r].Qj ← RegisterStat[rs].Qi} else {RS[r].Vj ← Regs[rs]; RS[r].Qj ← 0}; if (RegisterStat[rt].Qi≠0) {RS[r].Qk ← RegisterStat[rt].Qi} else {RS[r].Vk ← Regs[rt]; RS[r].Qk ← 0}; RS[r].Busy ← yes; RegisterStat[rd].Q ← r; </pre>
Load or store	Buffer r empty	<pre> if (RegisterStat[rs].Qi≠0) {RS[r].Qj ← RegisterStat[rs].Qi} else {RS[r].Vj ← Regs[rs]; RS[r].Qj ← 0}; RS[r].A ← imm; RS[r].Busy ← yes; </pre>
Load only		RegisterStat[rt].Qi ← r ;
Store only		<pre> if (RegisterStat[rt].Qi≠0) {RS[r].Qk ← RegisterStat[rs].Qi} else {RS[r].Vk ← Regs[rt]; RS[r].Qk ← 0}; </pre>
Execute FP operation	(RS[r].Qj = 0) and (RS[r].Qk = 0)	Compute result: operands are in Vj and Vk
Load/storestep 1	RS[r].Qj = 0 & r is head of load-store queue	RS[r].A ← RS[r].Vj + RS[r].A;
Load step 2	Load step 1 complete	Read from Mem[RS[r].A]
Write result FP operation or load	Execution complete at r & CDB available	<pre> ∀x(if (RegisterStat[x].Qi=r) {Regs[x] ← result; RegisterStat[x].Qi ← 0}); ∀x(if (RS[x].Qj=r) {RS[x].Vj ← result;RS[x].Qj ← 0}); ∀x(if (RS[x].Qk=r) {RS[x].Vk ← result;RS[x].Qk ← 0}); RS[r].Busy ← no; </pre>
Store	Execution complete at r & RS[r].Qk = 0	<pre> Mem[RS[r].A] ← RS[r].Vk; RS[r].Busy ← no; </pre>

Figure 3.13 Steps in the algorithm and what is required for each step. For the issuing instruction, rd is the destination, rs and rt are the source register numbers, imm is the sign-extended immediate field, and r is the reservation station or buffer that the instruction is assigned to. RS is the reservation station data structure. The value returned by an FP unit or by the load unit is called *result*. RegisterStat is the register status data structure (not the register file, which is *Regs[]*). When an instruction is issued, the destination register has its Qi field set to the number of the buffer or reservation station to which the instruction is issued. If the operands are available in the registers, they are stored in the V fields. Otherwise, the Q fields are set to indicate the reservation station that will produce the values needed as source operands. The instruction waits at the reservation station until both its operands are available, indicated by zero in the Q fields. The Q fields are set to zero either when this instruction is issued or when an instruction on which this instruction depends completes and does its write back. When an instruction has finished execution and the CDB is available, it can do its write back. All the buffers, registers, and reservation stations whose values of Qj or Qk are the same as the completing reservation station update their values from the CDB and mark the Q fields to indicate that values have been received. Thus the CDB can broadcast its result to many destinations in a single clock cycle, and if the waiting instructions have their operands, they can all begin execution on the next clock cycle. Loads go through two steps in execute, and stores perform slightly differently during Write Result, where they may have to wait for the value to store. Remember that, to preserve exception behavior, instructions should not be allowed to execute if a branch that is earlier in program order has not yet completed. Because no concept of program order is maintained after the issue stage, this restriction is usually implemented by preventing any instruction from leaving the issue step if there is a pending branch already in the pipeline. In [Section 3.6](#), we will see how speculation support removes this restriction.

Instruction		Instruction status			
		From iteration	Issue	Execute	Write result
f1d	f0,0(x1)	1	✓	✓	
fmul.d	f4,f0,f2	1	✓		
fsd	f4,0(x1)	1	✓

Qi	Load2		Mult2						

Figure 3.14 Two active iterations of the loop with no instruction yet completed. Entries in the multiplier reservation stations indicate that the outstanding loads are the sources. The store reservation stations indicate that the multiply destination is the source of the value to store.

- The load is before the store in program order and interchanging them results in a WAR hazard.
- The store is before the load in program order and interchanging them results in a RAW hazard.

Similarly, interchanging two stores to the same address results in a WAW hazard.

Therefore, to determine if a load can be executed at a given time, the processor can check whether any uncompleted store that precedes the load in program order

shares the same data memory address as the load. Similarly, a store must wait until there are no unexecuted loads or stores that are earlier in program order and share the same data memory address. We consider a method to eliminate this restriction in [Section 3.9](#).

To detect such hazards, the processor must have computed the data memory address associated with any earlier memory operation. A simple, but not necessarily optimal, way to guarantee that the processor has all such addresses is to perform the effective address calculations in program order. (We really only need to keep the relative order between stores and other memory references; that is, loads can be reordered freely.)

Let's consider the situation of a load first. If we perform effective address calculation in program order, then when a load has completed effective address calculation, we can check whether there is an address conflict by examining the A field of all active store buffers. If the load address matches the address of any active entries in the store buffer, that load instruction is not sent to the load buffer until the conflicting store completes. (Some implementations bypass the value directly to the load from a pending store, reducing the delay for this RAW hazard.)

Stores operate similarly, except that the processor must check for conflicts in both the load buffers and the store buffers because conflicting stores cannot be reordered with respect to either a load or a store.

A dynamically scheduled pipeline can yield very high performance, provided branches are predicted accurately—an issue we addressed in the previous section. The major drawback of this approach is the complexity of the Tomasulo scheme, which requires a large amount of hardware. In particular, each reservation station must contain an associative buffer, which must run at high speed, as well as complex control logic. The performance can also be limited by the single CDB. Although additional CDBs can be added, each CDB must interact with each reservation station, and the associative tag-matching hardware would have to be duplicated at each station for each CDB. In the 1990s, only high-end processors could take advantage of dynamic scheduling (and its extension to speculation); however, recently even processors designed for PMDs are using these techniques, and processors for high-end desktops and small servers have hundreds of buffers to support dynamic scheduling.

In Tomasulo's scheme, two different techniques are combined: the renaming of the architectural registers to a larger set of registers and the buffering of source operands from the register file. Source operand buffering resolves WAR hazards that arise when the operand is available in the registers. As we will see later, it is also possible to eliminate WAR hazards by the renaming of a register together with the buffering of a result until no outstanding references to the earlier version of the register remain. This approach will be used when we discuss hardware speculation.

Tomasulo's scheme was unused for many years after the 360/91, but was widely adopted in multiple-issue processors starting in the 1990s for several reasons:

1. Although Tomasulo's algorithm was designed before caches, the presence of caches, with the inherently unpredictable delays, has become one of the major motivations for dynamic scheduling. Out-of-order execution allows the processors to continue executing instructions while awaiting the completion of a cache miss, thus hiding all or part of the cache miss penalty.
2. As processors became more aggressive in their issue capability and designers were concerned with the performance of difficult-to-schedule code (such as most nonnumeric code), techniques such as register renaming, dynamic scheduling, and speculation became more important.
3. It can achieve high performance without requiring the compiler to target code to a specific pipeline structure, a valuable property in the era of shrink-wrapped mass market software.

3.6 Hardware-Based Speculation

As we try to exploit more instruction-level parallelism, maintaining control dependences becomes an increasing burden. Branch prediction reduces the direct stalls attributable to branches, but for a processor executing multiple instructions per clock, just predicting branches accurately may not be sufficient to generate the desired amount of instruction-level parallelism. A wide-issue processor may need to execute a branch every clock cycle to maintain maximum performance. Thus exploiting more parallelism requires that we overcome the limitation of control dependence.

Overcoming control dependence is done by speculating on the outcome of branches and executing the program as if our guesses are correct. This mechanism represents a subtle, but important, extension over branch prediction with dynamic scheduling. In particular, with speculation, we fetch, issue, and *execute* instructions, as if our branch predictions are always correct; dynamic scheduling only fetches and issues such instructions. Of course, we need mechanisms to handle the situation where the speculation is incorrect. Appendix H discusses a variety of mechanisms for supporting speculation by the compiler. In this section, we explore *hardware speculation*, which extends the ideas of dynamic scheduling.

Hardware-based speculation combines three key ideas: (1) dynamic branch prediction to choose which instructions to execute, (2) speculation to allow the execution of instructions before the control dependences are resolved (with the ability to undo the effects of an incorrectly speculated sequence), and (3) dynamic scheduling to deal with the scheduling of different combinations of basic blocks. (In comparison, dynamic scheduling without speculation only partially overlaps basic blocks because it requires that a branch be resolved before actually executing any instructions in the successor basic block.)

Hardware-based speculation follows the predicted flow of data values to choose when to execute instructions. This method of executing programs is essentially a *data flow execution*: Operations execute as soon as their operands are available.

To extend Tomasulo's algorithm to support speculation, we must separate the bypassing of results among instructions, which is needed to execute an instruction speculatively, from the actual completion of an instruction. By making this separation, we can allow an instruction to execute and to bypass its results to other instructions, without allowing the instruction to perform any updates that cannot be undone, until we know that the instruction is no longer speculative.

Using the bypassed value is like performing a speculative register read because we do not know whether the instruction providing the source register value is providing the correct result until the instruction is no longer speculative. When an instruction is no longer speculative, we allow it to update the register file or memory; we call this additional step in the instruction execution sequence *instruction commit*.

The key idea behind implementing speculation is to allow instructions to execute out of order but to force them to commit *in order* and to prevent any irrevocable action (such as updating state or taking an exception) until an instruction commits. Therefore, when we add speculation, we need to separate the process of completing execution from instruction commit, because instructions may finish execution considerably before they are ready to commit. Adding this commit phase to the instruction execution sequence requires an additional set of hardware buffers that hold the results of instructions that have finished execution but have not committed. This hardware buffer, which we call the *reorder buffer*, is also used to pass results among instructions that may be speculated.

The reorder buffer (ROB) provides additional registers in the same way as the reservation stations in Tomasulo's algorithm extend the register set. The ROB holds the result of an instruction between the time the operation associated with the instruction completes and the time the instruction commits. The ROB therefore is a source of operands for instructions, just as the reservation stations provide operands in Tomasulo's algorithm. The key difference is that in Tomasulo's algorithm, once an instruction writes its result, all subsequently issued instructions will find the result in the register file. With speculation, the register file is not updated until the instruction commits (and we know definitively that the instruction should execute); thus, the ROB supplies operands in the interval between completion of instruction execution and instruction commit. The ROB is similar to the store buffer in Tomasulo's algorithm, and we integrate the function of the store buffer into the ROB for simplicity.

Figure 3.15 shows the hardware structure of the processor including the ROB. Each entry in the ROB contains four fields: the instruction type, the destination field, the value field, and the ready field. The instruction type field indicates whether the instruction is a branch (and has no destination result), a store (which has a memory address destination), or a register operation (ALU operation or load, which has register destinations). The destination field supplies the register number (for loads

Figure 3.15 The basic structure of a FP unit using Tomasulo's algorithm and extended to handle speculation. Comparing this to [Figure 3.10](#) on [page 198](#), which implemented Tomasulo's algorithm, we can see that the major change is the addition of the ROB and the elimination of the store buffer, whose function is integrated into the ROB. This mechanism can be extended to allow multiple issues per clock by making the CDB wider to allow for multiple completions per clock.

and ALU operations) or the memory address (for stores) where the instruction result should be written. The value field is used to hold the value of the instruction result until the instruction commits. We will see an example of ROB entries shortly. Finally, the ready field indicates that the instruction has completed execution, and the value is ready.

The ROB subsumes the store buffers. Stores still execute in two steps, but the second step is performed by instruction commit. Although the renaming function of the reservation stations is replaced by the ROB, we still need a place to buffer operations (and operands) between the time they issue and the time they begin execution.

This function is still provided by the reservation stations. Because every instruction has a position in the ROB until it commits, we tag a result using the ROB entry number rather than using the reservation station number. This tagging requires that the ROB assigned for an instruction must be tracked in the reservation station. Later in this section, we will explore an alternative implementation that uses extra registers for renaming and a queue that replaces the ROB to decide when instructions can commit.

Here are the four steps involved in instruction execution:

1. *Issue*—Get an instruction from the instruction queue. Issue the instruction if there is an empty reservation station and an empty slot in the ROB; send the operands to the reservation station if they are available in either the registers or the ROB. Update the control entries to indicate the buffers are in use. The number of the ROB entry allocated for the result is also sent to the reservation station so that the number can be used to tag the result when it is placed on the CDB. If either all reservations are full or the ROB is full, then the instruction issue is stalled until both have available entries.
2. *Execute*—If one or more of the operands is not yet available, monitor the CDB while waiting for the register to be computed. This step checks for RAW hazards. When both operands are available at a reservation station, execute the operation. Instructions may take multiple clock cycles in this stage, and loads still require two steps in this stage. Stores only need the base register at this step, because execution for a store at this point is only effective address calculation.
3. *Write result*—When the result is available, write it on the CDB (with the ROB tag sent when the instruction issued) and from the CDB into the ROB, as well as to any reservation stations waiting for this result. Mark the reservation station as available. Special actions are required for store instructions. If the value to be stored is available, it is written into the Value field of the ROB entry for the store. If the value to be stored is not available yet, the CDB must be monitored until that value is broadcast, at which time the Value field of the ROB entry of the store is updated. For simplicity we assume that this occurs during the Write Result stage of a store; we discuss relaxing this requirement later.
4. *Commit*—This is the final stage of completing an instruction, after which only its result remains. (Some processors call this commit phase “completion” or “graduation.”) There are three different sequences of actions at commit depending on whether the committing instruction is a branch with an incorrect prediction, a store, or any other instruction (normal commit). The normal commit case occurs when an instruction reaches the head of the ROB and its result is present in the buffer; at this point, the processor updates the register with the result and removes the instruction from the ROB. Committing a store is similar except that memory is updated rather than a result register. When a branch with incorrect prediction reaches the head of the ROB, it indicates that the speculation was wrong. The ROB is flushed and execution is restarted at the correct successor of the branch. If the branch was correctly predicted, the branch is finished.

Once an instruction commits, its entry in the ROB is reclaimed, and the register or memory destination is updated, eliminating the need for the ROB entry. If the ROB fills, we simply stop issuing instructions until an entry is made free. Now let's examine how this scheme would work with the same example we used for Tomasulo's algorithm.

Example Assume the same latencies for the floating-point functional units as in earlier examples: add is 2 clock cycles, multiply is 6 clock cycles, and divide is 12 clock cycles. Using the following code segment, the same one we used to generate [Figure 3.12](#), show what the status tables look like when the `fmul.d` is ready to go to commit.

```
fld      f6,32(x2)
fld      f2,44(x3)
fmul.d   f0,f2,f4
fsub.d   f8,f2,f6
fdiv.d   f0,f0,f6
fadd.d   f6,f8,f2
```

Answer [Figure 3.16](#) shows the result in the three tables. Notice that although the `fsub.d` instruction has completed execution, it does not commit until the `fmul.d` commits. The reservation stations and register status field contain the same basic information that they did for Tomasulo's algorithm (see [page 200](#) for a description of those fields). The differences are that reservation station numbers are replaced with ROB entry numbers in the Qj and Qk fields, as well as in the register status fields, and we added the Dest field to the reservation stations. The Dest field designates the ROB entry that is the destination for the result produced by this reservation station entry.

The preceding example illustrates the key important difference between a processor with speculation and a processor with dynamic scheduling. Compare the content of [Figure 3.16](#) with that of [Figure 3.12](#) on page 184, which shows the same code sequence in operation on a processor with Tomasulo's algorithm. The key difference is that, in the preceding example, no instruction after the earliest uncompleted instruction (`fmul.d` in preceding example) is allowed to complete. In contrast, in [Figure 3.12](#) the `fsub.d` and `fadd.d` instructions have also completed.

One implication of this difference is that the processor with the ROB can dynamically execute code while maintaining a precise interrupt model. For example, if the `fmul.d` instruction caused an interrupt, we could simply wait until it reached the head of the ROB and take the interrupt, flushing any other pending instructions from the ROB. Because instruction commit happens in order, this yields a precise exception.

By contrast, in the example using Tomasulo's algorithm, the `fsub.d` and `fadd.d` instructions could both complete before the `fmul.d` raised the exception. The result is that the registers `f8` and `f6` (destinations of the `fsub.d` and

Reorder buffer						
Entry	Busy	Instruction		State	Destination	Value
1	No	f1d	f6,32(x2)	Commit	f6	Mem[32 + Regs[x2]]

Figure 3.16 At the time the `fmul.d` is ready to commit, only the two `f1d` instructions have committed, although several others have completed execution. The `fmul.d` is at the head of the ROB, and the two `f1d` instructions are there only to ease understanding. The `fsub.d` and `fadd.d` instructions will not commit until the `fmul.d` instruction commits, although the results of the instructions are available and can be used as sources for other instructions. The `fdiv.d` is in execution, but has not completed solely because of its longer latency than that of `fmul.d`. The Value column indicates the value being held; the format #X is used to refer to a value field of ROB entry X. Reorder buffers 1 and 2 are actually completed but are shown for informational purposes. We do not show the entries for the load/store queue, but these entries are kept in order.

`fadd.d` instructions) could be overwritten, in which case the interrupt would be imprecise.

Some users and architects have decided that imprecise floating-point exceptions are acceptable in high-performance processors because the program will likely terminate; see Appendix J for further discussion of this topic. Other types

of exceptions, such as page faults, are much more difficult to accommodate if they are imprecise because the program must transparently resume execution after handling such an exception.

The use of a ROB with in-order instruction commit provides precise exceptions, in addition to supporting speculative execution, as the next example shows.

Example Consider the code example used earlier for Tomasulo's algorithm and shown in [Figure 3.14](#) in execution:

```

Loop: fld      f0,0(x1)
      fmul.d   f4,f0,f2
      fsd      f4,0(x1)
      addi     x1,x1,-8
      bne      x1,x2,Loop    //branches if x1≠x2

```

Assume that we have issued all the instructions in the loop twice. Let's also assume that the `fld` and `fmul.d` from the first iteration have committed and all other instructions have completed execution. Normally, the store would wait in the ROB for both the effective address operand (`x1` in this example) and the value (`f4` in this example). Because we are only considering the floating-point pipeline, assume the effective address for the store is computed by the time the instruction is issued.

Answer [Figure 3.17](#) shows the result in two tables.

Because neither the register values nor any memory values are actually written until an instruction commits, the processor can easily undo its speculative actions when a branch is found to be mispredicted. Suppose that the branch `bne` is not taken the first time in [Figure 3.17](#). The instructions prior to the branch will simply commit when each reaches the head of the ROB; when the branch reaches the head of that buffer, the buffer is simply cleared and the processor begins fetching instructions from the other path.

In practice, processors that speculate try to recover as early as possible after a branch is mispredicted. This recovery can be done by clearing the ROB for all entries that appear after the mispredicted branch, allowing those that are before the branch in the ROB to continue, and restarting the fetch at the correct branch successor. In speculative processors, performance is more sensitive to the branch prediction because the impact of a misprediction will be higher. Thus all the aspects of handling branches—prediction accuracy, latency of misprediction detection, and misprediction recovery time—increase in importance.

Exceptions are handled by not recognizing the exception until it is ready to commit. If a speculated instruction raises an exception, the exception is recorded in the ROB. If a branch misprediction arises and the instruction should not have been executed, the exception is flushed along with the instruction when the

Figure 3.17 Only the fld and fmul.d instructions have committed, although all the others have completed execution. Thus no reservation stations are busy and none are shown. The remaining instructions will be committed as quickly as possible. The first two reorder buffers are empty, but are shown for completeness.

ROB is cleared. If the instruction reaches the head of the ROB, then we know it is no longer speculative and the exception should really be taken. We can also try to handle exceptions as soon as they arise and all earlier branches are resolved, but this is more challenging in the case of exceptions than for branch mispredict and, because it occurs less frequently, not as critical.

Figure 3.18 shows the steps of execution for an instruction, as well as the conditions that must be satisfied to proceed to the step and the actions taken. We show the case where mispredicted branches are not resolved until commit. Although speculation seems like a simple addition to dynamic scheduling, a comparison of Figure 3.18 with the comparable figure for Tomasulo's algorithm in Figure 3.13 shows that speculation adds significant complications to the control. In addition, remember that branch mispredictions are somewhat more complex.

There is an important difference in how stores are handled in a speculative processor versus in Tomasulo's algorithm. In Tomasulo's algorithm, a store can update memory when it reaches Write Result (which ensures that the effective address has been calculated) and the data value to store is available. In a speculative processor, a store updates memory only when it reaches the head of

Status	Wait until	Action or bookkeeping
Issue all instructions	Reservation station (<i>r</i>) and ROB (<i>b</i>) both available	<pre> if (RegisterStat[rs].Busy) /*in-flight instr. writes rs*/ {h ← RegisterStat[rs].Reorder; if (ROB[h].Ready) /* Instr completed already */ {RS[r].Vj ← ROB[h].Value; RS[r].Qj ← 0;} else {RS[r].Qj ← h;} /* wait for instruction */ } else {RS[r].Vj ← Regs[rs]; RS[r].Qj ← 0;}; RS[r].Busy ← yes; RS[r].Dest ← b; ROB[b].Instruction ← opcode; ROB[b].Dest ← rd; ROB[b].Ready ← no; </pre>

Load step 2	Load step 1 done and all stores earlier in ROB have different address	Read from Mem[RS[r].A]
Store	(RS[r].Qj == 0) and store at queue head	ROB[h].Address ← RS[r].Vj + RS[r].A;
Write result all but store	Execution done at <i>r</i> and CDB available	<pre> b ← RS[r].Dest; RS[r].Busy ← no; ∀x (if (RS[x].Qj==b) {RS[x].Vj ← result; RS[x].Qj ← 0}); ∀x (if (RS[x].Qk==b) {RS[x].Vk ← result; RS[x].Qk ← 0}); ROB[b].Value ← result; ROB[b].Ready ← yes; </pre>
Store	Execution done at <i>r</i> and (RS[r].Qk == 0)	ROB[h].Value ← RS[r].Vk;
Commit	Instruction is at the head of the ROB (entry <i>h</i>) and ROB[h].ready == yes	<pre> d ← ROB[h].Dest; /* register dest, if exists */ if (ROB[h].Instruction==Branch) {if (branch is mispredicted) {clear ROB[h], RegisterStat; fetch branch dest;};} else if (ROB[h].Instruction==Store) {Mem[ROB[h].Destination] ← ROB[h].Value;} else /* put the result in the register destination */ {Regs[d] ← ROB[h].Value;}; ROB[h].Busy ← no; /* free up ROB entry */ /* free up dest register if no one else writing it */ if (RegisterStat[d].Reorder==h) {RegisterStat[d].Busy ← no;}; </pre>

Figure 3.18 Steps in the algorithm and what is required for each step. For the issuing instruction, *rd* is the destination, *rs* and *rt* are the sources, *r* is the reservation station allocated, *b* is the assigned ROB entry, and *h* is the head entry of the ROB. *RS* is the reservation station data structure. The value returned by a reservation station is called the *result*. *Register-Stat* is the register data structure, *Regs* represents the actual registers, and *ROB* is the reorder buffer data structure.

the ROB. This difference ensures that memory is not updated until an instruction is no longer speculative.

Figure 3.18 has one significant simplification for stores, which is unneeded in practice. Figure 3.18 requires stores to wait in the Write Result stage for the register source operand whose value is to be stored; the value is then moved from the *Vk* field of the store's reservation station to the Value field of the store's ROB entry. In reality, however, the value to be stored need not arrive until *just before* the store commits and can be placed directly into the store's ROB entry by the sourcing instruction. This is accomplished by having the hardware track when the source value to be stored is available in the store's ROB entry and searching the ROB on every instruction completion to look for dependent stores.

This addition is not complicated, but adding it has two effects: we would need to add a field to the ROB, and Figure 3.18, which is already in a small font, would be even longer! Although Figure 3.18 makes this simplification, in our examples, we will allow the store to pass through the Write Result stage and simply wait for the value to be ready when it commits.

Like Tomasulo's algorithm, we must avoid hazards through memory. WAW and WAR hazards through memory are eliminated with speculation because the actual updating of memory occurs in order, when a store is at the head of the ROB, so no earlier loads or stores can still be pending. RAW hazards through memory are maintained by two restrictions:

1. Not allowing a load to initiate the second step of its execution if any active ROB entry occupied by a store has a Destination field that matches the value of the A field of the load
2. Maintaining the program order for the computation of an effective address of a load with respect to all earlier stores

Together, these two restrictions ensure that any load that accesses a memory location written to by an earlier store cannot perform the memory access until the store has written the data. Some speculative processors will actually bypass the value from the store to the load directly when such a RAW hazard occurs. Another approach is to predict potential collisions using a form of value prediction; we consider this in Section 3.9.

Although this explanation of speculative execution has focused on floating point, the techniques easily extend to the integer registers and functional units. Indeed, because such programs tend to have code where the branch behavior is less predictable, speculation may be more useful in integer programs. Additionally, these techniques can be extended to work in a multiple-issue processor by allowing multiple instructions to issue and commit every clock. In fact, speculation is probably most interesting in such processors because less ambitious techniques can probably exploit sufficient ILP within basic blocks when assisted by a compiler.

3.7

Exploiting ILP Using Multiple Issue and Static Scheduling

The techniques of the preceding sections can be used to eliminate data, control stalls, and achieve an ideal CPI of one. To improve performance further, we want to decrease the CPI to less than one, but the CPI cannot be reduced below one if we issue only one instruction every clock cycle.

The goal of the *multiple-issue processors*, discussed in the next few sections, is to allow multiple instructions to issue in a clock cycle. Multiple-issue processors come in three major flavors:

1. Statically scheduled superscalar processors
2. VLIW (very long instruction word) processors
3. Dynamically scheduled superscalar processors

The two types of superscalar processors issue varying numbers of instructions per clock and use in-order execution if they are statically scheduled or out-of-order execution if they are dynamically scheduled.

VLIW processors, in contrast, issue a fixed number of instructions formatted either as one large instruction or as a fixed instruction packet with the parallelism among instructions explicitly indicated by the instruction. VLIW processors are inherently statically scheduled by the compiler. When Intel and HP created the IA-64 architecture, described in Appendix H, they also introduced the name EPIC (explicitly parallel instruction computer) for this architectural style.

Although statically scheduled superscalars issue a varying rather than a fixed number of instructions per clock, they are actually closer in concept to VLIWs because both approaches rely on the compiler to schedule code for the processor. Because of the diminishing advantages of a statically scheduled superscalar as the issue width grows, statically scheduled superscalars are used primarily for narrow issue widths, normally just two instructions. Beyond that width, most designers choose to implement either a VLIW or a dynamically scheduled superscalar. Because of the similarities in hardware and required compiler technology, we focus on VLIWs in this section, and we will see them again in [Chapter 7](#). The insights of this section are easily extrapolated to a statically scheduled superscalar.

[Figure 3.19](#) summarizes the basic approaches to multiple issue and their distinguishing characteristics and shows processors that use each approach.

The Basic VLIW Approach

VLIWs use multiple, independent functional units. Rather than attempting to issue multiple, independent instructions to the units, a VLIW packages the multiple operations into one very long instruction or requires that the instructions in the

Common name	Issue structure	Hazard detection	Scheduling	Distinguishing characteristic	Examples
Superscalar (static)	Dynamic	Hardware	Static	In-order execution	Mostly in the embedded space: MIPS and ARM, including the Cortex-A53
Superscalar (dynamic)	Dynamic	Hardware	Dynamic	Some out-of-order execution, but no speculation	None at the present
Superscalar (speculative)	Dynamic	Hardware	Dynamic with speculation	Out-of-order execution with speculation	Intel Core i3, i5, i7; AMD Phenom; IBM Power 7
VLIW/LIW	Static	Primarily software	Static	All hazards determined and indicated by compiler (often implicitly)	Most examples are in signal processing, such as the TI C6x
EPIC	Primarily static	Primarily software	Mostly static	All hazards determined and indicated explicitly by the compiler	Itanium

Figure 3.19 The five primary approaches in use for multiple-issue processors and the primary characteristics that distinguish them. This chapter has focused on the hardware-intensive techniques, which are all some form of superscalar. Appendix H focuses on compiler-based approaches. The EPIC approach, as embodied in the IA-64 architecture, extends many of the concepts of the early VLIW approaches, providing a blend of static and dynamic approaches.

issue packet satisfy the same constraints. Because there is no fundamental difference in the two approaches, we will just assume that multiple operations are placed in one instruction, as in the original VLIW approach.

Because the advantage of a VLIW increases as the maximum issue rate grows, we focus on a wider issue processor. Indeed, for simple two-issue processors, the overhead of a superscalar is probably minimal. Many designers would probably argue that a four-issue processor has manageable overhead, but as we will see later in this chapter, the growth in overhead is a major factor limiting wider issue processors.

Let's consider a VLIW processor with instructions that contain five operations, including one integer operation (which could also be a branch), two floating-point operations, and two memory references. The instruction would have a set of fields for each functional unit—perhaps 16–24 bits per unit, yielding an instruction length of between 80 and 120 bits. By comparison, the Intel Itanium 1 and 2 contain six operations per instruction packet (i.e., they allow concurrent issue of two three-instruction bundles, as Appendix H describes).

To keep the functional units busy, there must be enough parallelism in a code sequence to fill the available operation slots. This parallelism is uncovered by unrolling loops and scheduling the code within the single larger loop body. If the unrolling generates straight-line code, then *local scheduling* techniques, which operate on a single basic block, can be used. If finding and exploiting the parallelism require scheduling code across branches, a substantially more complex *global*

scheduling algorithm must be used. Global scheduling algorithms are not only more complex in structure, but they also must deal with significantly more complicated trade-offs in optimization, because moving code across branches is expensive.

In Appendix H, we discuss *trace scheduling*, one of these global scheduling techniques developed specifically for VLIWs; we will also explore special hardware support that allows some conditional branches to be eliminated, extending the usefulness of local scheduling and enhancing the performance of global scheduling.

For now, we will rely on loop unrolling to generate long, straight-line code sequences so that we can use local scheduling to build up VLIW instructions and focus on how well these processors operate.

Example Suppose we have a VLIW that could issue two memory references, two FP operations, and one integer operation or branch in every clock cycle. Show an unrolled version of the loop $x[i] = x[i] + s$ (see page 158 for the RISC-V code) for such a processor. Unroll as many times as necessary to eliminate any stalls.

Answer Figure 3.20 shows the code. The loop has been unrolled to make seven copies of the body, which eliminates all stalls (i.e., completely empty issue cycles), and runs in 9 cycles for the unrolled and scheduled loop. This code yields a running rate of seven results in 9 cycles, or 1.29 cycles per result, nearly twice as fast as the two-issue superscalar of Section 3.2 that used unrolled and scheduled code.

Memory reference 1	Memory reference 2	FP operation 1	FP operation 2	Integer operation/branch
fld f0,0(x1)	fld f6,-8(x1)			
fld f10,-16(x1)	fld f14,-24(x1)			
fld f18,-32(x1)	fld f22,-40(x1)	fadd.d f4,f0,f2	fadd.d f8,f6,f2	
fld f26,-48(x1)		fadd.d f12,f0,f2	fadd.d f16,f14,f2	
		fadd.d f20,f18,f2	fadd.d f24,f22,f2	
fsd f4,0(x1)	fsd f8,-8(x1)	fadd.d f28,f26,f24		
fsd f12,-16(x1)	fsd f16,-24(x1)			addi x1,x1,-56
fsd f20,24(x1)	fsd f24,16(x1)			
fsd f28,8(x1)				bne x1,x2,Loop

Figure 3.20 VLIW instructions that occupy the inner loop and replace the unrolled sequence. This code takes 9 cycles assuming correct branch prediction. The issue rate is 23 operations in 9 clock cycles, or 2.5 operations per cycle. The efficiency, the percentage of available slots that contained an operation, is about 60%. To achieve this issue rate requires a larger number of registers than RISC-V would normally use in this loop. The preceding VLIW code sequence requires at least eight FP registers, whereas the same code sequence for the base RISC-V processor can use as few as two FP registers or as many as five when unrolled and scheduled.

For the original VLIW model, there were both technical and logistical problems that made the approach less efficient. The technical problems were the increase in code size and the limitations of the lockstep operation. Two different elements combine to increase code size substantially for a VLIW. First, generating enough operations in a straight-line code fragment requires ambitiously unrolling loops (as in earlier examples), thereby increasing code size. Second, whenever instructions are not full, the unused functional units translate to wasted bits in the instruction encoding. In Appendix H, we examine software scheduling approaches, such as software pipelining, that can achieve the benefits of unrolling without as much code expansion.

To combat this code size increase, clever encodings are sometimes used. For example, there may be only one large immediate field for use by any functional unit. Another technique is to compress the instructions in main memory and expand them when they are read into the cache or are decoded. In Appendix H, we show other techniques, as well as document the significant code expansion seen in IA-64.

Early VLIWs operated in lockstep; there was no hazard-detection hardware at all. This structure dictated that a stall in any functional unit pipeline must cause the entire processor to stall because all the functional units had to be kept synchronized. Although a compiler might have been able to schedule the deterministic functional units to prevent stalls, predicting which data accesses would encounter a cache stall and scheduling them were very difficult to do. Thus caches needed to be blocking and causing *all* the functional units to stall. As the issue rate and number of memory references became large, this synchronization restriction became unacceptable. In more recent processors, the functional units operate more independently, and the compiler is used to avoid hazards at issue time, while hardware checks allow for unsynchronized execution once instructions are issued.

Binary code compatibility has also been a major logistical problem for general-purpose VLIWs or those that run third-party software. In a strict VLIW approach, the code sequence makes use of both the instruction set definition and the detailed pipeline structure, including both functional units and their latencies. Thus different numbers of functional units and unit latencies require different versions of the code. This requirement makes migrating between successive implementations, or between implementations with different issue widths, more difficult than it is for a superscalar design. Of course, obtaining improved performance from a new superscalar design may require recompilation. Nonetheless, the ability to run old binary files is a practical advantage for the superscalar approach. In the domain-specific architectures, which we examine in [Chapter 7](#), this problem is not serious because applications are written specifically for an architectural configuration.

The EPIC approach, of which the IA-64 architecture is the primary example, provides solutions to many of the problems encountered in early general-purpose VLIW designs, including extensions for more aggressive software speculation and methods to overcome the limitation of hardware dependence while preserving binary compatibility.

The major challenge for all multiple-issue processors is to try to exploit large amounts of ILP. When the parallelism comes from unrolling simple loops in FP

programs, the original loop probably could have been run efficiently on a vector processor (described in the next chapter). It is not clear that a multiple-issue processor is preferred over a vector processor for such applications; the costs are similar, and the vector processor is typically the same speed or faster. The potential advantages of a multiple-issue processor versus a vector processor are the former's ability to extract some parallelism from less structured code and to easily cache all forms of data. For these reasons, multiple-issue approaches have become the primary method for taking advantage of instruction-level parallelism, and vectors have become primarily an extension to these processors.

3.8

Exploiting ILP Using Dynamic Scheduling, Multiple Issue, and Speculation

So far we have seen how the individual mechanisms of dynamic scheduling, multiple issue, and speculation work. In this section, we put all three together, which yields a microarchitecture quite similar to those in modern microprocessors. For simplicity we consider only an issue rate of two instructions per clock, but the concepts are no different from modern processors that issue three or more instructions per clock.

Let's assume we want to extend Tomasulo's algorithm to support multiple-issue superscalar pipeline with separate integer, load/store, and floating-point units (both FP multiply and FP add), each of which can initiate an operation on every clock. We do not want to issue instructions to the reservation stations out of order because this could lead to a violation of the program semantics. To gain the full advantage of dynamic scheduling, we will allow the pipeline to issue any combination of two instructions in a clock, using the scheduling hardware to actually assign operations to the integer and floating-point unit. Because the interaction of the integer and floating-point instructions is crucial, we also extend Tomasulo's scheme to deal with both the integer and floating-point functional units and registers, as well as incorporating speculative execution. As [Figure 3.21](#) shows, the basic organization is similar to that of a processor with speculation with one issue per clock, except that the issue and completion logic must be enhanced to allow multiple instructions to be processed per clock.

Issuing multiple instructions per clock in a dynamically scheduled processor (with or without speculation) is very complex for the simple reason that the multiple instructions may depend on one another. Because of this, the tables must be updated for the instructions in parallel; otherwise, the tables will be incorrect or the dependence may be lost.

Two different approaches have been used to issue multiple instructions per clock in a dynamically scheduled processor, and both rely on the observation that the key is assigning a reservation station and updating the pipeline control tables. One approach is to run this step in half a clock cycle so that two instructions can be processed in one clock cycle; this approach cannot be easily extended to handle four instructions per clock, unfortunately.

Figure 3.21 The basic organization of a multiple issue processor with speculation. In this case, the organization could allow a FP multiply, FP add, integer, and load/store to all issues simultaneously (assuming one issue per clock per functional unit). Note that several datapaths must be widened to support multiple issues: the CDB, the operand buses, and, critically, the instruction issue logic, which is not shown in this figure. The last is a difficult problem, as we discuss in the text.

A second alternative is to build the logic necessary to handle two or more instructions at once, including any possible dependences between the instructions. Modern superscalar processors that issue four or more instructions per clock may include both approaches: They both pipeline and widen the issue logic. A key observation is that we cannot simply pipeline away the problem. By making instruction issues take multiple clocks because new instructions are issuing every clock cycle, we must be able to assign the reservation station and to update the pipeline tables so that a dependent instruction issuing on the next clock can use the updated information.

This issue step is one of the most fundamental bottlenecks in dynamically scheduled superscalars. To illustrate the complexity of this process, [Figure 3.22](#) shows the issue logic for one case: issuing a load followed by a dependent FP operation. The logic is based on that in [Figure 3.18](#) on page 197, but represents only one case. In a modern superscalar, every possible combination of dependent instructions that is allowed to issue in the same clock cycle must be considered. Because the number of possibilities climbs as the square of the number of instructions that can be issued in a clock, the issue step is a likely bottleneck for attempts to go beyond four instructions per clock.

We can generalize the detail of [Figure 3.22](#) to describe the basic strategy for updating the issue logic and the reservation tables in a dynamically scheduled superscalar with up to n issues per clock as follows:

1. Assign a reservation station and a reorder buffer for *every* instruction that *might* be issued in the next issue bundle. This assignment can be done before the instruction types are known simply by preallocating the reorder buffer entries sequentially to the instructions in the packet using n available reorder buffer entries and by ensuring that enough reservation stations are available to issue the whole bundle, independent of what it contains. By limiting the number of instructions of a given class (say, one FP, one integer, one load, one store), the necessary reservation stations can be preallocated. Should sufficient reservation stations not be available (such as when the next few instructions in the program are all of one instruction type), the bundle is broken, and only a subset of the instructions, in the original program order, is issued. The remainder of the instructions in the bundle can be placed in the next bundle for potential issue.
2. Analyze all the dependences among the instructions in the issue bundle.
3. If an instruction in the bundle depends on an earlier instruction in the bundle, use the assigned reorder buffer number to update the reservation table for the dependent instruction. Otherwise, use the existing reservation table and reorder buffer information to update the reservation table entries for the issuing instruction.

Of course, what makes the preceding very complicated is that it is all done in parallel in a single clock cycle!

At the back-end of the pipeline, we must be able to complete and commit multiple instructions per clock. These steps are somewhat easier than the issue problems because multiple instructions that can actually commit in the same clock cycle must have already dealt with and resolved any dependences. As we will see, designers have figured out how to handle this complexity: The Intel i7, which we examine in [Section 3.12](#), uses essentially the scheme we have described for speculative multiple issue, including a large number of reservation stations, a reorder buffer, and a load and store buffer that is also used to handle nonblocking cache misses.

From a performance viewpoint, we can show how the concepts fit together with an example.

Action or bookkeeping	Comments
<pre> if (RegisterStat[rs1].Busy) /* in-flight instr. writes rs */ { h ← RegisterStat[rs1].Reorder; if (ROB[h].Ready) /* Instr completed already */ { RS[x1].Vj ← ROB[h].Value; RS[x1].Qj ← 0; } else { RS[x1].Qj ← h; } /* wait for instruction */ } else { RS[x1].Vj ← Regs[rs]; RS[x1].Qj ← 0; }; RS[x1].Busy ← yes; RS[x1].Dest ← b1; ROB[b1].Instruction ← Load; ROB[b1].Dest ← rd1; ROB[b1].Ready ← no; RS[r].A ← imm1; RegisterStat[rt1].Reorder ← b1; RegisterStat[rt1].Busy ← yes; ROB[b1].Dest ← rt1; </pre>	<p>Updating the reservation tables for the load instruction, which has a single source operand. Because this is the first instruction in this issue bundle, it looks no different than what would normally happen for a load.</p>
<pre> RS[x2].Qj ← b1; } /* wait for load instruction */ </pre>	<p>Because we know that the first operand of the FP operation is from the load, this step simply updates the reservation station to point to the load. Notice that the dependence must be analyzed on the fly and the ROB entries must be allocated during this issue step so that the reservation tables can be correctly updated.</p>
<pre> if (RegisterStat[rt2].Busy) /* in-flight instr writes rt */ { h ← RegisterStat[rt2].Reorder; if (ROB[h].Ready) /* Instr completed already */ { RS[x2].Vk ← ROB[h].Value; RS[x2].Qk ← 0; } else { RS[x2].Qk ← h; } /* wait for instruction */ } else { RS[x2].Vk ← Regs[rt2]; RS[x2].Qk ← 0; }; RegisterStat[rd2].Reorder ← b2; RegisterStat[rd2].Busy ← yes; ROB[b2].Dest ← rd2; </pre>	<p>Because we assumed that the second operand of the FP instruction was from a prior issue bundle, this step looks like it would in the single-issue case. Of course, if this instruction were dependent on something in the same issue bundle, the tables would need to be updated using the assigned reservation buffer.</p>
<pre> RS[x2].Busy ← yes; RS[x2].Dest ← b2; ROB[b2].Instruction ← FP operation; ROB[b2].Dest ← rd2; ROB[b2].Ready ← no; </pre>	<p>This section simply updates the tables for the FP operation and is independent of the load. Of course, if further instructions in this issue bundle depended on the FP operation (as could happen with a four-issue superscalar), the updates to the reservation tables for those instructions would be effected by this instruction.</p>

Figure 3.22 The issue steps for a pair of dependent instructions (called 1 and 2), where instruction 1 is FP load and instruction 2 is an FP operation whose first operand is the result of the load instruction; x1 and x2 are the assigned reservation stations for the instructions; and b1 and b2 are the assigned reorder buffer entries. For the issuing instructions, rd1 and rd2 are the destinations; rs1, rs2, and rt2 are the sources (the load has only one source); x1 and x2 are the reservation stations allocated; and b1 and b2 are the assigned ROB entries. RS is the reservation station data structure. RegisterStat is the register data structure, Regs represents the actual registers, and ROB is the reorder buffer data structure. Notice that we need to have assigned reorder buffer entries for this logic to operate properly, and recall that all these updates happen in a single clock cycle in parallel, not sequentially.

Example Consider the execution of the following loop, which increments each element of an integer array, on a two-issue processor, once without speculation and once with speculation:

```

Loop: ld    x2,0(x1)    //x2=array element
      addi  x2,x2,1     //increment x2
      sd    x2,0(x1)    //store result
      addi  x1,x1,8     //increment pointer
      bne   x2,x3,Loop  //branch if not last

```

Assume that there are separate integer functional units for effective address calculation, for ALU operations, and for branch condition evaluation. Create a table for the first three iterations of this loop for both processors. Assume that up to two instructions of any type can commit per clock.

Answer Figures 3.23 and 3.24 show the performance for a two-issue, dynamically scheduled processor, without and with speculation. In this case, where a branch

Iteration number	Instructions	Issues at clock cycle number	Executes at clock cycle number	Memory access at clock cycle number	Write CDB at clock cycle number	Comment
1	ld x2,0(x1)	1	2	3	4	First issue
1	addi x2,x2,1	1	5		6	Wait for ld
1	sd x2,0(x1)	2	3	7		Wait for addi
1	addi x1,x1,8	2	3		4	Execute directly
1	bne x2,x3,Loop	3	7			Wait for addi
2	ld x2,0(x1)	4	8	9	10	Wait for bne
2	addi x2,x2,1	4	11		12	Wait for ld
2	sd x2,0(x1)	5	9	13		Wait for addi
2	addi x1,x1,8	5	8		9	Wait for bne
2	bne x2,x3,Loop	6	13			Wait for addi
3	ld x2,0(x1)	7	14	15	16	Wait for bne
3	addi x2,x2,1	7	17		18	Wait for ld
3	sd x2,0(x1)	8	15	19		Wait for addi
3	addi x1,x1,8	8	14		15	Wait for bne
3	bne x2,x3,Loop	9	19			Wait for addi

Figure 3.23 The time of issue, execution, and writing result for a dual-issue version of our pipeline *without speculation*. Note that the ld following the bne cannot start execution earlier because it must wait until the branch outcome is determined. This type of program, with data-dependent branches that cannot be resolved earlier, shows the strength of speculation. Separate functional units for address calculation, ALU operations, and branch-condition evaluation allow multiple instructions to execute in the same cycle. Figure 3.24 shows this example with speculation.

Iteration number	Instructions	Issues at clock number	Executes at clock number	Read access at clock number	Write CDB at clock number	Commits at clock number	Comment
1	ld x2,0(x1)	1	2	3	4	5	First issue
1	addi x2,x2,1	1	5		6	7	Wait for ld
1	sd x2,0(x1)	2	3			7	Wait for addi
1	addi x1,x1,8	2	3		4	8	Commit in order
1	bne x2,x3,Loop	3	7			8	Wait for addi
2	ld x2,0(x1)	4	5	6	7	9	No execute delay
2	addi x2,x2,1	4	8		9	10	Wait for ld
2	sd x2,0(x1)	5	6			10	Wait for addi
2	addi x1,x1,8	5	6		7	11	Commit in order
2	bne x2,x3,Loop	6	10			11	Wait for addi
3	ld x2,0(x1)	7	8	9	10	12	Earliest possible
3	addi x2,x2,1	7	11		12	13	Wait for ld
3	sd x2,0(x1)	8	9			13	Wait for addi
3	addi x1,x1,8	8	9		10	14	Executes earlier
3	bne x2,x3,Loop	9	13			14	Wait for addi

Figure 3.24 The time of issue, execution, and writing result for a dual-issue version of our pipeline *with speculation*. Note that the ld following the bne can start execution early because it is speculative.

can be a critical performance limiter, speculation helps significantly. The third branch in the speculative processor executes in clock cycle 13, whereas it executes in clock cycle 19 on the nonspeculative pipeline. Because the completion rate on the nonspeculative pipeline is falling behind the issue rate rapidly, the nonspeculative pipeline will stall when a few more iterations are issued. The performance of the nonspeculative processor could be improved by allowing load instructions to complete effective address calculation before a branch is decided, but unless speculative memory accesses are allowed, this improvement will gain only 1 clock per iteration.

This example clearly shows how speculation can be advantageous when there are data-dependent branches, which otherwise would limit performance. This advantage depends, however, on accurate branch prediction. Incorrect speculation does not improve performance; in fact, it typically harms performance and, as we shall see, dramatically lowers energy efficiency.

3.9

Advanced Techniques for Instruction Delivery and Speculation

In a high-performance pipeline, especially one with multiple issues, predicting branches well is not enough; we actually have to be able to deliver a high-bandwidth instruction stream. In recent multiple-issue processors, this has meant delivering 4–8 instructions every clock cycle. We look at methods for increasing instruction delivery bandwidth first. We then turn to a set of key issues in implementing advanced speculation techniques, including the use of register renaming versus reorder buffers, the aggressiveness of speculation, and a technique called *value prediction*, which attempts to predict the result of a computation and which could further enhance ILP.

Increasing Instruction Fetch Bandwidth

A multiple-issue processor will require that the average number of instructions fetched every clock cycle be at least as large as the average throughput. Of course, fetching these instructions requires wide enough paths to the instruction cache, but the most difficult aspect is handling branches. In this section, we look at two methods for dealing with branches and then discuss how modern processors integrate the instruction prediction and prefetch functions.

Branch-Target Buffers

To reduce the branch penalty for our simple five-stage pipeline, as well as for deeper pipelines, we must know whether the as-yet-undecoded instruction is a branch and, if so, what the next program counter (PC) should be. If the instruction is a branch and we know what the next PC should be, we can have a branch penalty of zero. A branch-prediction cache that stores the predicted address for the next instruction after a branch is called a *branch-target buffer* or *branch-target cache*. [Figure 3.25](#) shows a branch-target buffer.

Because a branch-target buffer predicts the next instruction address and will send it out *before* decoding the instruction, we *must* know whether the fetched instruction is predicted as a taken branch. If the PC of the fetched instruction matches an address in the prediction buffer, then the corresponding predicted PC is used as the next PC. The hardware for this branch-target buffer is essentially identical to the hardware for a cache.

If a matching entry is found in the branch-target buffer, fetching begins immediately at the predicted PC. Note that unlike a branch-prediction buffer, the predictive entry must be matched to this instruction because the predicted PC will be sent

Figure 3.25 A branch-target buffer. The PC of the instruction being fetched is matched against a set of instruction addresses stored in the first column; these represent the addresses of known branches. If the PC matches one of these entries, then the instruction being fetched is a taken branch, and the second field, predicted PC, contains the prediction for the next PC after the branch. Fetching begins immediately at that address. The third field, which is optional, may be used for extra prediction state bits.

out before it is known whether this instruction is even a branch. If the processor did not check whether the entry matched this PC, then the wrong PC would be sent out for instructions that were not branches, resulting in worse performance. We need to store only the predicted-taken branches in the branch-target buffer because an untaken branch should simply fetch the next sequential instruction, as if it were not a branch.

Figure 3.26 shows the steps when using a branch-target buffer for a simple five-stage pipeline. As we can see in this figure, there will be no branch delay if a branch-prediction entry is found in the buffer and the prediction is correct. Otherwise, there will be a penalty of at least two clock cycles. Dealing with the mispredictions and misses is a significant challenge because we typically will have to halt instruction fetch while we rewrite the buffer entry. Thus we want to make this process fast to minimize the penalty.

Figure 3.26 The steps involved in handling an instruction with a branch-target buffer.

To evaluate how well a branch-target buffer works, we first must determine the penalties in all possible cases. Figure 3.27 contains this information for a simple five-stage pipeline.

Example Determine the total branch penalty for a branch-target buffer assuming the penalty cycles for individual mispredictions in Figure 3.27. Make the following assumptions about the prediction accuracy and hit rate:

- Prediction accuracy is 90% (for instructions in the buffer).
- Hit rate in the buffer is 90% (for branches predicted taken).

Answer We compute the penalty by looking at the probability of two events: the branch is predicted taken but ends up being not taken, and the branch is taken but is not found in the buffer. Both carry a penalty of two cycles.

$$\begin{aligned}
 \text{Probability (branch in buffer, but actually not taken)} &= \text{Percent buffer hit rate} \\
 &\quad \times \text{Percent incorrect predictions} \\
 &= 90\% \times 10\% = 0.09 \\
 \text{Probability (branch not in buffer, but actually taken)} &= 10\% \\
 \text{Branch penalty} &= (0.09 + 0.10) \times 2 \\
 \text{Branch penalty} &= 0.38
 \end{aligned}$$

The improvement from dynamic branch prediction will grow as the pipeline length, and thus the branch delay grows; in addition, better predictors will yield a greater performance advantage. Modern high-performance processors have branch misprediction delays on the order of 15 clock cycles; clearly, accurate prediction is critical!

One variation on the branch-target buffer is to store one or more *target instructions* instead of, or in addition to, the predicted *target address*. This variation has two potential advantages. First, it allows the branch-target buffer access to take longer than the time between successive instruction fetches, possibly allowing a larger branch-target buffer. Second, buffering the actual target instructions allows us to perform an optimization called *branch folding*. Branch folding can be used to obtain 0-cycle unconditional branches and sometimes 0-cycle conditional branches. As we will see, the Cortex A-53 uses a single-entry branch target cache that stores the predicted target instructions.

Consider a branch-target buffer that buffers instructions from the predicted path and is being accessed with the address of an unconditional branch. The only function of the unconditional branch is to change the PC. Thus, when the branch-target buffer signals a hit and indicates that the branch is

Instruction in buffer	Prediction	Actual branch	Penalty cycles
Yes	Taken	Taken	0
Yes	Taken	Not taken	2
No		Taken	2
No		Not taken	0

Figure 3.27 Penalties for all possible combinations of whether the branch is in the buffer and what it actually does, assuming we store only taken branches in the buffer. There is no branch penalty if everything is correctly predicted and the branch is found in the target buffer. If the branch is not correctly predicted, the penalty is equal to 1 clock cycle to update the buffer with the correct information (during which an instruction cannot be fetched) and 1 clock cycle, if needed, to restart fetching the next correct instruction for the branch. If the branch is not found and taken, a 2-cycle penalty is encountered, during which time the buffer is updated.

unconditional, the pipeline can simply substitute the instruction from the branch-target buffer in place of the instruction that is returned from the cache (which is the unconditional branch). If the processor is issuing multiple instructions per cycle, then the buffer will need to supply multiple instructions to obtain the maximum benefit. In some cases, it may be possible to eliminate the cost of a conditional branch.

Specialized Branch Predictors: Predicting Procedure Returns, Indirect Jumps, and Loop Branches

As we try to increase the opportunity and accuracy of speculation, we face the challenge of predicting indirect jumps, that is, jumps whose destination address varies at runtime. High-level language programs will generate such jumps for indirect procedure calls, select or case statements, and FORTRAN-computed gotos, although many indirect jumps simply come from procedure returns. For example, for the SPEC95 benchmarks, procedure returns account for more than 15% of the branches and the vast majority of the indirect jumps on average. For object-oriented languages such as C++ and Java, procedure returns are even more frequent. Thus focusing on procedure returns seems appropriate.

Though procedure returns can be predicted with a branch-target buffer, the accuracy of such a prediction technique can be low if the procedure is called from multiple sites and the calls from one site are not clustered in time. For example, in SPEC CPU95, an aggressive branch predictor achieves an accuracy of less than 60% for such return branches. To overcome this problem, some designs use a small buffer of return addresses operating as a stack. This structure caches the most recent return addresses, pushing a return address on the stack at a call and popping one off at a return. If the cache is sufficiently large (i.e., as large as the maximum call depth), it will predict the returns perfectly. [Figure 3.28](#) shows the performance of such a return buffer with 0–16 elements for a number of the SPEC CPU95 benchmarks. We will use a similar return predictor when we examine the studies of ILP in [Section 3.10](#). Both the Intel Core processors and the AMD Phenom processors have return address predictors.

In large server applications, indirect jumps also occur for various function calls and control transfers. Predicting the targets of such branches is not as simple as in a procedure return. Some processors have opted to add specialized predictors for all indirect jumps, whereas others rely on a branch target buffer.

Although a simple predictor like gshare does a good job of predicting many conditional branches, it is not tailored to predicting loop branches, especially for long running loops. As we observed earlier, the Intel Core i7 920 used a specialized loop branch predictor. With the emergence of tagged hybrid predictors, which are as good at predicting loop branches, some recent designers have opted to put the resources into larger tagged hybrid predictors rather than a separate loop branch predictor.

Figure 3.28 Prediction accuracy for a return address buffer operated as a stack on a number of SPEC CPU95 benchmarks. The accuracy is the fraction of return addresses predicted correctly. A buffer of 0 entries implies that the standard branch prediction is used. Because call depths are typically not large, with some exceptions, a modest buffer works well. These data come from [Skadron et al. \(1999\)](#) and use a fix-up mechanism to prevent corruption of the cached return addresses.

Integrated Instruction Fetch Units

To meet the demands of multiple-issue processors, many recent designers have chosen to implement an integrated instruction fetch unit as a separate autonomous unit that feeds instructions to the rest of the pipeline. Essentially, this amounts to recognizing that characterizing instruction fetch as a simple single pipe stage given the complexities of multiple issue is no longer valid.

Instead, recent designs have used an integrated instruction fetch unit that integrates several functions:

1. *Integrated branch prediction*—The branch predictor becomes part of the instruction fetch unit and is constantly predicting branches, so as to drive the fetch pipeline.

2. *Instruction prefetch*—To deliver multiple instructions per clock, the instruction fetch unit will likely need to fetch ahead. The unit autonomously manages the prefetching of instructions (see [Chapter 2](#) for a discussion of techniques for doing this), integrating it with branch prediction.
3. *Instruction memory access and buffering*—When fetching multiple instructions per cycle, a variety of complexities are encountered, including the difficulty that fetching multiple instructions may require accessing multiple cache lines. The instruction fetch unit encapsulates this complexity, using prefetch to try to hide the cost of crossing cache blocks. The instruction fetch unit also provides buffering, essentially acting as an on-demand unit to provide instructions to the issue stage as needed and in the quantity needed.

Virtually all high-end processors now use a separate instruction fetch unit connected to the rest of the pipeline by a buffer containing pending instructions.

Speculation: Implementation Issues and Extensions

In this section, we explore five issues that involve the design trade-offs and challenges in multiple-issue and speculation, starting with the use of register renaming, the approach that is sometimes used instead of a reorder buffer. We then discuss one important possible extension to speculation on control flow: an idea called value prediction.

Speculation Support: Register Renaming Versus Reorder Buffers

One alternative to the use of a reorder buffer (ROB) is the explicit use of a larger physical set of registers combined with register renaming. This approach builds on the concept of renaming used in Tomasulo's algorithm and extends it. In Tomasulo's algorithm, the values of the *architecturally visible registers* (x0, . . . r31 and f0, . . . f31) are contained, at any point in execution, in some combination of the register set and the reservation stations. With the addition of speculation, register values may also temporarily reside in the ROB. In either case, if the processor does not issue new instructions for a period of time, all existing instructions will commit, and the register values will appear in the register file, which directly corresponds to the architecturally visible registers.

In the register-renaming approach, an extended set of physical registers is used to hold both the architecturally visible registers as well as temporary values. Thus the extended registers replace most of the function of the ROB and the reservation stations; only a queue to ensure that instructions complete in order is needed. During instruction issue, a renaming process maps the names of architectural registers to physical register numbers in the extended register set, allocating a new unused register for the destination. WAW and WAR hazards are avoided by renaming of the destination register, and speculation recovery is handled

because a physical register holding an instruction destination does not become the architectural register until the instruction commits.

The *renaming map* is a simple data structure that supplies the physical register number of the register that currently corresponds to the specified architectural register, a function performed by the register status table in Tomasulo's algorithm. When an instruction commits, the renaming table is permanently updated to indicate that a physical register corresponds to the actual architectural register, thus effectively finalizing the update to the processor state. Although an ROB is not necessary with register renaming, the hardware must still track instructions in a queue-like structure and update the renaming table in strict order.

An advantage of the renaming approach versus the ROB approach is that instruction commit is slightly simplified because it requires only two simple actions: (1) record that the mapping between an architectural register number and physical register number is no longer speculative, and (2) free up any physical registers being used to hold the "older" value of the architectural register. In a design with reservation stations, a station is freed up when the instruction using it completes execution, and a ROB entry is freed up when the corresponding instruction commits.

With register renaming, deallocating registers is more complex because before we free up a physical register, we must know that it no longer corresponds to an architectural register and that no further uses of the physical register are outstanding. A physical register corresponds to an architectural register until the architectural register is rewritten, causing the renaming table to point elsewhere. That is, if no renaming entry points to a particular physical register, then it no longer corresponds to an architectural register. There may, however, still be outstanding uses of the physical register. The processor can determine whether this is the case by examining the source register specifiers of all instructions in the functional unit queues. If a given physical register does not appear as a source and it is not designated as an architectural register, it may be reclaimed and reallocated.

Alternatively, the processor can simply wait until another instruction that writes the same architectural register commits. At that point, there can be no further uses of the older value outstanding. Although this method may tie up a physical register slightly longer than necessary, it is easy to implement and is used in most recent superscalars.

One question you may be asking is how do we ever know which registers are the architectural registers if they are constantly changing? Most of the time when the program is executing, it does not matter. There are clearly cases, however, where another process, such as the operating system, must be able to know exactly where the contents of a certain architectural register reside. To understand how this capability is provided, assume the processor does not issue instructions for some period of time. Eventually all instructions in the pipeline will commit, and the mapping between the architecturally visible registers and physical registers will become stable. At that point, a subset of the physical registers contains the architecturally visible registers, and the value of any physical register not associated with an architectural register is unneeded. It is then easy to move the architectural

registers to a fixed subset of physical registers so that the values can be communicated to another process.

Both register renaming and reorder buffers continue to be used in high-end processors, which now feature the ability to have as many as 100 or more instructions (including loads and stores waiting on the cache) in flight. Whether renaming or a reorder buffer is used, the key complexity bottleneck for a dynamically scheduled superscalar remains issuing bundles of instructions with dependences within the bundle. In particular, dependent instructions in an issue bundle must be issued with the assigned virtual registers of the instructions on which they depend. A strategy for instruction issue with register renaming similar to that used for multiple issue with reorder buffers (see page 205) can be deployed, as follows:

1. The issue logic reserves enough physical registers for the entire issue bundle (say, four registers for a four-instruction bundle with at most one register result per instruction).
2. The issue logic determines what dependences exist within the bundle. If a dependence does not exist within the bundle, the register renaming structure is used to determine the physical register that holds, or will hold, the result on which instruction depends. When no dependence exists within the bundle, the result is from an earlier issue bundle, and the register renaming table will have the correct register number.
3. If an instruction depends on an instruction that is earlier in the bundle, then the pre-reserved physical register in which the result will be placed is used to update the information for the issuing instruction.

Note that just as in the reorder buffer case, the issue logic must both determine dependences within the bundle and update the renaming tables in a single clock, and as before, the complexity of doing this for a larger number of instructions per clock becomes a chief limitation in the issue width.

The Challenge of More Issues per Clock

Without speculation, there is little motivation to try to increase the issue rate beyond two, three, or possibly four issues per clock because resolving branches would limit the average issue rate to a smaller number. Once a processor includes accurate branch prediction and speculation, we might conclude that increasing the issue rate would be attractive. Duplicating the functional units is straightforward assuming silicon capacity and power; the real complications arise in the issue step and correspondingly in the commit step. The Commit step is the dual of the issue step, and the requirements are similar, so let's take a look at what has to happen for a six-issue processor using register renaming.

Figure 3.29 shows a six-instruction code sequence and what the issue step must do. Remember that this must all occur in a single clock cycle, if the processor is to maintain a peak rate of six issues per clock! All the dependences must be detected,

Instr. #	Instruction	Physical register assigned or destination	Instruction with physical register numbers	Rename map changes
1	add x1, x2, x3	p32	add p32, p2, p3	x1-> p32
2	sub x1, x1, x2	p33	sub p33, p32, p2	x1->p33
3	add x2, x1, x2	p34	add p34, p33, x2	x2->p34
4	sub x1, x3, x2	p35	sub p35, p3, p34	x1->p35
5	add x1, x1, x2	p36	add p36, p35, p34	x1->p36
6	sub x1, x3, x1	p37	sub p37, p3, p36	x1->p37

Figure 3.29 An example of six instructions to be issued in the same clock cycle and what has to happen. The instructions are shown in program order: 1–6; they are, however, issued in 1 clock cycle! The notation *p_i* is used to refer to a physical register; the contents of that register at any point is determined by the renaming map. For simplicity, we assume that the physical registers holding the architectural registers *x1*, *x2*, and *x3* are initially *p1*, *p2*, and *p3* (they could be any physical register). The instructions are issued with physical register numbers, as shown in column four. The rename map, which appears in the last column, shows how the map would change if the instructions were issued sequentially. The difficulty is that all this renaming and replacement of architectural registers by physical renaming registers happens effectively in 1 cycle, not sequentially. The issue logic must find all the dependencies and “rewrite” the instruction in parallel.

the physical registers must be assigned, and the instructions must be rewritten using the physical register numbers: in one clock. This example makes it clear why issue rates have grown from 3–4 to only 4–8 in the past 20 years. The complexity of the analysis required during the issue cycle grows as the square of the issue width, and a new processor is typically targeted to have a higher clock rate than in the last generation! Because register renaming and the reorder buffer approaches are duals, the same complexities arise independent of the implementation scheme.

How Much to Speculate

One of the significant advantages of speculation is its ability to uncover events that would otherwise stall the pipeline early, such as cache misses. This potential advantage, however, comes with a significant potential disadvantage. Speculation is not free. It takes time and energy, and the recovery of incorrect speculation further reduces performance. In addition, to support the higher instruction execution rate needed to benefit from speculation, the processor must have additional resources, which take silicon area and power. Finally, if speculation causes an exceptional event to occur, such as a cache or translation lookaside buffer (TLB) miss, the potential for significant performance loss increases, if that event would not have occurred without speculation.

To maintain most of the advantage while minimizing the disadvantages, most pipelines with speculation will allow only low-cost exceptional events (such as a first-level cache miss) to be handled in speculative mode. If an expensive exceptional event occurs, such as a second-level cache miss or a TLB miss, the processor will wait

until the instruction causing the event is no longer speculative before handling the event. Although this may slightly degrade the performance of some programs, it avoids significant performance losses in others, especially those that suffer from a high frequency of such events coupled with less-than-excellent branch prediction.

In the 1990s the potential downsides of speculation were less obvious. As processors have evolved, the real costs of speculation have become more apparent, and the limitations of wider issue and speculation have been obvious. We return to this issue shortly.

Speculating Through Multiple Branches

In the examples we have considered in this chapter, it has been possible to resolve a branch before having to speculate on another. Three different situations can benefit from speculating on multiple branches simultaneously: (1) a very high branch frequency, (2) significant clustering of branches, and (3) long delays in functional units. In the first two cases, achieving high performance may mean that multiple branches are speculated, and it may even mean handling more than one branch per clock. Database programs and other less structured integer computations, often exhibit these properties, making speculation on multiple branches important. Likewise, long delays in functional units can raise the importance of speculating on multiple branches as a way to avoid stalls from the longer pipeline delays.

Speculating on multiple branches slightly complicates the process of speculation recovery but is straightforward otherwise. As of 2017, no processor has yet combined full speculation with resolving multiple branches per cycle, and it is unlikely that the costs of doing so would be justified in terms of performance versus complexity and power.

Speculation and the Challenge of Energy Efficiency

What is the impact of speculation on energy efficiency? At first glance, one might argue that using speculation always decreases energy efficiency because whenever speculation is wrong, it consumes excess energy in two ways:

1. Instructions that are speculated and whose results are not needed generate excess work for the processor, wasting energy.
2. Undoing the speculation and restoring the state of the processor to continue execution at the appropriate address consumes additional energy that would not be needed without speculation.

Certainly, speculation will raise the power consumption, and if we could control speculation, it would be possible to measure the cost (or at least the dynamic power cost). But, if speculation lowers the execution time by more than it increases the average power consumption, then the total energy consumed may be less.

Thus, to understand the impact of speculation on energy efficiency, we need to look at how often speculation is leading to unnecessary work. If a significant number of unneeded instructions is executed, it is unlikely that speculation will

Figure 3.30 The fraction of instructions that are executed as a result of misspeculation is typically much higher for integer programs (the first five) versus FP programs (the last five).

improve running time by a comparable amount. [Figure 3.30](#) shows the fraction of instructions that are executed from misspeculation for a subset of the SPEC2000 benchmarks using a sophisticated branch predictor. As we can see, this fraction of executed misspeculated instructions is small in scientific code and significant (about 30% on average) in integer code. Thus it is unlikely that speculation is energy-efficient for integer applications, and the end of Dennard scaling makes imperfect speculation more problematic. Designers could avoid speculation, try to reduce the misspeculation, or think about new approaches, such as only speculating on branches that are known to be highly predictable.

Address Aliasing Prediction

Address aliasing prediction is a technique that predicts whether two stores or a load and a store refer to the same memory address. If two such references do not refer to the same address, then they may be safely interchanged. Otherwise, we must wait until the memory addresses accessed by the instructions are known. Because we need not actually predict the address values, only whether such values conflict, the prediction can be reasonably accurate with small predictors. Address prediction relies on the ability of a speculative processor to recover after a misprediction; that is, if the actual addresses that were predicted to be different (and thus not alias) turn out to be the same (and thus are aliases), the processor simply restarts the sequence,

just as though it had mispredicted a branch. Address value speculation has been used in several processors already and may become universal in the future.

Address prediction is a simple and restricted form of *value prediction*, which attempts to predict the value that will be produced by an instruction. Value prediction could, if it were highly accurate, eliminate data flow restrictions and achieve higher rates of ILP. Despite many researchers focusing on value prediction in the past 15 years in dozens of papers, the results have never been sufficiently attractive to justify general value prediction in real processors.

3.10

Cross-Cutting Issues

Hardware Versus Software Speculation

The hardware-intensive approaches to speculation in this chapter and the software approaches of Appendix H provide alternative approaches to exploiting ILP. Some of the trade-offs, and the limitations, for these approaches are listed here:

- To speculate extensively, we must be able to disambiguate memory references. This capability is difficult to do at compile time for integer programs that contain pointers. In a hardware-based scheme, dynamic runtime disambiguation of memory addresses is done using the techniques we saw earlier for Tomasulo's algorithm. This disambiguation allows us to move loads past stores at runtime. Support for speculative memory references can help overcome the conservatism of the compiler, but unless such approaches are used carefully, the overhead of the recovery mechanisms may swamp the advantages.
- Hardware-based speculation works better when control flow is unpredictable and when hardware-based branch prediction is superior to software-based branch prediction done at compile time. These properties hold for many integer programs, where the misprediction rates for dynamic predictors are usually less than one-half of those for static predictors. Because speculated instructions may slow down the computation when the prediction is incorrect, this difference is significant. One result of this difference is that even statically scheduled processors normally include dynamic branch predictors.
- Hardware-based speculation maintains a completely precise exception model even for speculated instructions. Recent software-based approaches have added special support to allow this as well.
- Hardware-based speculation does not require compensation or bookkeeping code, which is needed by ambitious software speculation mechanisms.
- Compiler-based approaches may benefit from the ability to see further into the code sequence, resulting in better code scheduling than a purely hardware-driven approach.
- Hardware-based speculation with dynamic scheduling does not require different code sequences to achieve good performance for different implementations

of an architecture. Although this advantage is the hardest to quantify, it may be the most important one in the long run. Interestingly, this was one of the motivations for the IBM 360/91. On the other hand, more recent explicitly parallel architectures, such as IA-64, have added flexibility that reduces the hardware dependence inherent in a code sequence.

The major disadvantage of supporting speculation in hardware is the complexity and additional hardware resources required. This hardware cost must be evaluated against both the complexity of a compiler for a software-based approach and the amount and usefulness of the simplifications in a processor that relies on such a compiler.

Some designers have tried to combine the dynamic and compiler-based approaches to achieve the best of each. Such a combination can generate interesting and obscure interactions. For example, if conditional moves are combined with register renaming, a subtle side effect appears. A conditional move that is annulled must still copy a value to the destination register because it was renamed earlier in the instruction pipeline. These subtle interactions complicate the design and verification process and can also reduce performance.

The Intel Itanium processor was the most ambitious computer ever designed based on the software support for ILP and speculation. It did not deliver on the hopes of the designers, especially for general-purpose, nonscientific code. As designers' ambitions for exploiting ILP were reduced in light of the difficulties described on page 244, most architectures settled on hardware-based mechanisms with issue rates of three to four instructions per clock.

Speculative Execution and the Memory System

Inherent in processors that support speculative execution or conditional instructions is the possibility of generating invalid addresses that would not occur without speculative execution. Not only would this be incorrect behavior if protection exceptions were taken, but also the benefits of speculative execution would be swamped by false exception overhead. Therefore the memory system must identify speculatively executed instructions and conditionally executed instructions and suppress the corresponding exception.

By similar reasoning, we cannot allow such instructions to cause the cache to stall on a miss because, again, unnecessary stalls could overwhelm the benefits of speculation. Thus these processors must be matched with nonblocking caches.

In reality, the penalty of a miss that goes to DRAM is so large that speculated misses are handled only when the next level is on-chip cache (L2 or L3). Figure 2.5 on page 84 shows that for some well-behaved scientific programs, the compiler can sustain multiple outstanding L2 misses to cut the L2 miss penalty effectively. Once again, for this to work, the memory system behind the cache must match the goals of the compiler in number of simultaneous memory accesses.

3.11

Multithreading: Exploiting Thread-Level Parallelism to Improve Uniprocessor Throughput

The topic we cover in this section, multithreading, is truly a cross-cutting topic, because it has relevance to pipelining and superscalars, to graphics processing units ([Chapter 4](#)), and to multiprocessors ([Chapter 5](#)). A *thread* is like a process in that it has state and a current program counter, but threads typically share the address space of a single process, allowing a thread to easily access data of other threads within the same process. Multithreading is a technique whereby multiple threads share a processor without requiring an intervening process switch. The ability to switch between threads rapidly is what enables multithreading to be used to hide pipeline and memory latencies.

In the next chapter, we will see how multithreading provides the same advantages in GPUs. Finally, [Chapter 5](#) will explore the combination of multithreading and multiprocessing. These topics are closely interwoven because multithreading is a primary technique for exposing more parallelism to the hardware. In a strict sense, multithreading uses thread-level parallelism, and thus is properly the subject of [Chapter 5](#), but its role in both improving pipeline utilization and in GPUs motivates us to introduce the concept here.

Although increasing performance by using ILP has the great advantage that it is reasonably transparent to the programmer, as we have seen, ILP can be quite limited or difficult to exploit in some applications. In particular, with reasonable instruction issue rates, cache misses that go to memory or off-chip caches are unlikely to be hidden by available ILP. Of course, when the processor is stalled waiting on a cache miss, the utilization of the functional units drops dramatically.

Because attempts to cover long memory stalls with more ILP have limited effectiveness, it is natural to ask whether other forms of parallelism in an application could be used to hide memory delays. For example, an online transaction processing system has natural parallelism among the multiple queries and updates that are presented by requests. Of course, many scientific applications contain natural parallelism because they often model the three-dimensional, parallel structure of nature, and that structure can be exploited by using separate threads. Even desktop applications that use modern Windows-based operating systems often have multiple active applications running, providing a source of parallelism.

Multithreading allows multiple threads to share the functional units of a single processor in an overlapping fashion. In contrast, a more general method to exploit *thread-level parallelism* (TLP) is with a multiprocessor that has multiple independent threads operating at once and in parallel. Multithreading, however, does not duplicate the entire processor as a multiprocessor does. Instead, multithreading shares most of the processor core among a set of threads, duplicating only private state, such as the registers and program counter. As we will see in [Chapter 5](#), many recent processors incorporate both multiple processor cores on a single chip and provide multithreading within each core.

Duplicating the per-thread state of a processor core means creating a separate register file and a separate PC for each thread. The memory itself can be shared through the virtual memory mechanisms, which already support multiprogramming. In addition, the hardware must support the ability to change to a different thread relatively quickly; in particular, a thread switch should be much more efficient than a process switch, which typically requires hundreds to thousands of processor cycles. Of course, for multithreading hardware to achieve performance improvements, a program must contain multiple threads (we sometimes say that the application is multithreaded) that could execute in concurrent fashion. These threads are identified either by a compiler (typically from a language with parallelism constructs) or by the programmer.

There are three main hardware approaches to multithreading: fine-grained, coarse-grained, and simultaneous. *Fine-grained multithreading* switches between threads on each clock cycle, causing the execution of instructions from multiple threads to be interleaved. This interleaving is often done in a round-robin fashion, skipping any threads that are stalled at that time. One key advantage of fine-grained multithreading is that it can hide the throughput losses that arise from both short and long stalls because instructions from other threads can be executed when one thread stalls, even if the stall is only for a few cycles. The primary disadvantage of fine-grained multithreading is that it slows down the execution of an individual thread because a thread that is ready to execute without stalls will be delayed by instructions from other threads. It trades an increase in multithreaded throughput for a loss in the performance (as measured by latency) of a single thread.

The SPARC T1 through T5 processors (originally made by Sun, now made by Oracle and Fujitsu) use fine-grained multithreading. These processors were targeted at multithreaded workloads such as transaction processing and web services. The T1 supported 8 cores per processor and 4 threads per core, while the T5 supports 16 cores and 128 threads per core. Later versions (T2–T5) also supported 4–8 processors. The NVIDIA GPUs, which we look at in the next chapter, also make use of fine-grained multithreading.

Coarse-grained multithreading was invented as an alternative to fine-grained multithreading. Coarse-grained multithreading switches threads only on costly stalls, such as level two or three cache misses. Because instructions from other threads will be issued only when a thread encounters a costly stall, coarse-grained multithreading relieves the need to have thread-switching be essentially free and is much less likely to slow down the execution of any one thread.

Coarse-grained multithreading suffers, however, from a major drawback: it is limited in its ability to overcome throughput losses, especially from shorter stalls. This limitation arises from the pipeline start-up costs of coarse-grained multithreading. Because a processor with coarse-grained multithreading issues instructions from a single thread, when a stall occurs, the pipeline will see a bubble before the new thread begins executing. Because of this start-up overhead, coarse-grained multithreading is much more useful for reducing the penalty of very high-cost stalls, where pipeline refill is negligible compared to the stall time. Several research

projects have explored coarse-grained multithreading, but no major current processors use this technique.

The most common implementation of multithreading is called *simultaneous multithreading* (SMT). Simultaneous multithreading is a variation on fine-grained multithreading that arises naturally when fine-grained multithreading is implemented on top of a multiple-issue, dynamically scheduled processor. As with other forms of multithreading, SMT uses thread-level parallelism to hide long-latency events in a processor, thereby increasing the usage of the functional units. The key insight in SMT is that register renaming and dynamic scheduling allow multiple instructions from independent threads to be executed without regard to the dependences among them; the resolution of the dependences can be handled by the dynamic scheduling capability.

Figure 3.31 conceptually illustrates the differences in a processor's ability to exploit the resources of a superscalar for the following processor configurations:

- A superscalar with no multithreading support
- A superscalar with coarse-grained multithreading

Figure 3.31 How four different approaches use the functional unit execution slots of a superscalar processor. The horizontal dimension represents the instruction execution capability in each clock cycle. The vertical dimension represents a sequence of clock cycles. An empty (white) box indicates that the corresponding execution slot is unused in that clock cycle. The shades of gray and black correspond to four different threads in the multithreading processors. Black is also used to indicate the occupied issue slots in the case of the superscalar without multithreading support. The Sun T1 and T2 (aka Niagara) processors are fine-grained, multithreaded processors, while the Intel Core i7 and IBM Power7 processors use SMT. The T2 has 8 threads, the Power7 has 4, and the Intel i7 has 2. In all existing SMTs, instructions issue from only one thread at a time. The difference in SMT is that the subsequent decision to execute an instruction is decoupled and could execute the operations coming from several different instructions in the same clock cycle.

- A superscalar with fine-grained multithreading
- A superscalar with simultaneous multithreading

In the superscalar without multithreading support, the use of issue slots is limited by a lack of ILP, including ILP to hide memory latency. Because of the length of L2 and L3 cache misses, much of the processor can be left idle.

In the coarse-grained multithreaded superscalar, the long stalls are partially hidden by switching to another thread that uses the resources of the processor. This switching reduces the number of completely idle clock cycles. In a coarse-grained multithreaded processor, however, thread switching occurs only when there is a stall. Because the new thread has a start-up period, there are likely to be some fully idle cycles remaining.

In the fine-grained case, the interleaving of threads can eliminate fully empty slots. In addition, because the issuing thread is changed on every clock cycle, longer latency operations can be hidden. Because instruction issue and execution are connected, a thread can issue only as many instructions as are ready. With a narrow issue width, this is not a problem (a cycle is either occupied or not), which is why fine-grained multithreading works perfectly for a single issue processor, and SMT would make no sense. Indeed, in the Sun T2, there are two issues per clock, but they are from different threads. This eliminates the need to implement the complex dynamic scheduling approach and relies instead on hiding latency with more threads.

If one implements fine-grained threading on top of a multiple-issue, dynamically schedule processor, the result is SMT. In all existing SMT implementations, all issues come from one thread, although instructions from different threads can initiate execution in the same cycle, using the dynamic scheduling hardware to determine what instructions are ready. Although [Figure 3.31](#) greatly simplifies the real operation of these processors, it does illustrate the potential performance advantages of multithreading in general and SMT in wider issue, dynamically scheduled processors.

Simultaneous multithreading uses the insight that a dynamically scheduled processor already has many of the hardware mechanisms needed to support the mechanism, including a large virtual register set. Multithreading can be built on top of an out-of-order processor by adding a per-thread renaming table, keeping separate PCs, and providing the capability for instructions from multiple threads to commit.

Effectiveness of Simultaneous Multithreading on Superscalar Processors

A key question is, how much performance can be gained by implementing SMT? When this question was explored in 2000–2001, researchers assumed that dynamic superscalars would get much wider in the next five years, supporting six to eight issues per clock with speculative dynamic scheduling, many simultaneous loads and stores, large primary caches, and four to eight contexts with simultaneous issue

and retirement from multiple contexts. No processor has gotten close to this combination.

As a result, simulation research results that showed gains for multiprogrammed workloads of two or more times are unrealistic. In practice, the existing implementations of SMT offer only two to four contexts with fetching and issue from only one, and up to four issues per clock. The result is that the gain from SMT is also more modest.

[Esmaeilzadeh et al. \(2011\)](#) did an extensive and insightful set of measurements that examined both the performance and energy benefits of using SMT in a single i7 920 core running a set of multithreaded applications. The Intel i7 920 supported SMT with two threads per core, as does the recent i7 6700. The changes between the i7 920 and the 6700 are relatively small and are unlikely to significantly change the results as shown in this section.

The benchmarks used consist of a collection of parallel scientific applications and a set of multithreaded Java programs from the DaCapo and SPEC Java suite, as summarized in [Figure 3.32](#). [Figure 3.31](#) shows the ratios of performance and energy efficiency for these benchmarks when run on one core of a i7 920 with SMT turned off and on. (We plot the energy efficiency ratio, which is the inverse of energy consumption, so that, like speedup, a higher ratio is better.)

The harmonic mean of the speedup for the Java benchmarks is 1.28, despite the two benchmarks that see small gains. These two benchmarks, *pjbb2005* and *tradebeans*, while multithreaded, have limited parallelism. They are included because they are typical of a multithreaded benchmark that might be run on an SMT processor with the hope of extracting some performance, which they find in limited amounts. The PARSEC benchmarks obtain somewhat better speedups than the full set of Java benchmarks (harmonic mean of 1.31). If *tradebeans* and *pjbb2005* were omitted, the Java workload would actually have significantly better speedup (1.39) than the PARSEC benchmarks. (See the discussion of the implication of using harmonic mean to summarize the results in the caption of [Figure 3.33](#).)

Energy consumption is determined by the combination of speedup and increase in power consumption. For the Java benchmarks, on average, SMT delivers the same energy efficiency as non-SMT (average of 1.0), but it is brought down by the two poor performing benchmarks; without *pjbb2005* and *tradebeans*, the average energy efficiency for the Java benchmarks is 1.06, which is almost as good as the PARSEC benchmarks. In the PARSEC benchmarks, SMT reduces energy by $1 - (1/1.08) = 7\%$. Such energy-reducing performance enhancements are *very difficult* to find. Of course, the static power associated with SMT is paid in both cases, thus the results probably slightly overstate the energy gains.

These results clearly show that SMT with extensive support in an aggressive speculative processor can improve performance in an energy-efficient fashion. In 2011, the balance between offering multiple simpler cores and fewer more sophisticated cores has shifted in favor of more cores, with each core typically being a three- to four-issue superscalar with SMT supporting two to four threads. Indeed, [Esmaeilzadeh et al. \(2011\)](#) show that the energy improvements from SMT are even larger on the Intel i5 (a processor similar to the i7, but with smaller caches and a

Figure 3.32 The parallel benchmarks used here to examine multithreading, as well as in [Chapter 5](#) to examine multiprocessing with an i7. The top half of the chart consists of PARSEC benchmarks collected by [Bienia et al. \(2008\)](#). The PARSEC benchmarks are meant to be indicative of compute-intensive, parallel applications that would be appropriate for multicore processors. The lower half consists of multithreaded Java benchmarks from the DaCapo collection (see [Blackburn et al., 2006](#)) and pjbb2005 from SPEC. All of these benchmarks contain some parallelism; other Java benchmarks in the DaCapo and SPEC Java workloads use multiple threads but have little or no true parallelism and, hence, are not used here. See [Esmaeilzadeh et al. \(2011\)](#) for additional information on the characteristics of these benchmarks, relative to the measurements here and in [Chapter 5](#).

lower clock rate) and the Intel Atom (an 80x86 processor originally designed for the netbook and PMD market, now focused on low-end PCs, and described in [Section 3.13](#)).

3.12

Putting It All Together: The Intel Core i7 6700 and ARM Cortex-A53

In this section, we explore the design of two multiple issue processors: the ARM Cortex-A53 core, which is used as the basis for several tablets and cell phones, and the Intel Core i7 6700, a high-end, dynamically scheduled, speculative processor intended for high-end desktops and server applications. We begin with the simpler processor.

Figure 3.33 The speedup from using multithreading on one core on an i7 processor averages 1.28 for the Java benchmarks and 1.31 for the PARSEC benchmarks (using an unweighted harmonic mean, which implies a workload where the total time spent executing each benchmark in the single-threaded base set was the same). The energy efficiency averages 0.99 and 1.07, respectively (using the harmonic mean). Recall that anything above 1.0 for energy efficiency indicates that the feature reduces execution time by more than it increases average power. Two of the Java benchmarks experience little speedup and have significant negative energy efficiency because of this issue. Turbo Boost is off in all cases. These data were collected and analyzed by [Esmaeilzadeh et al. \(2011\)](#) using the Oracle (Sun) HotSpot build 16.3-b01 Java 1.6.0 Virtual Machine and the gcc v4.4.1 native compiler.

The ARM Cortex-A53

The A53 is a dual-issue, statically scheduled superscalar with dynamic issue detection, which allows the processor to issue two instructions per clock. [Figure 3.34](#) shows the basic pipeline structure of the pipeline. For nonbranch, integer instructions, there are eight stages: F1, F2, D1, D2, D3/ISS, EX1, EX2, and WB, as described in the caption. The pipeline is in order, so an instruction can initiate execution only when its results are available and when proceeding instructions have initiated. Thus, if the next two instructions are dependent, both can proceed to the appropriate execution pipeline, but they will be serialized when they get to the beginning of that pipeline. When the scoreboard-based issue logic indicates that the result from the first instruction is available, the second instruction can issue.

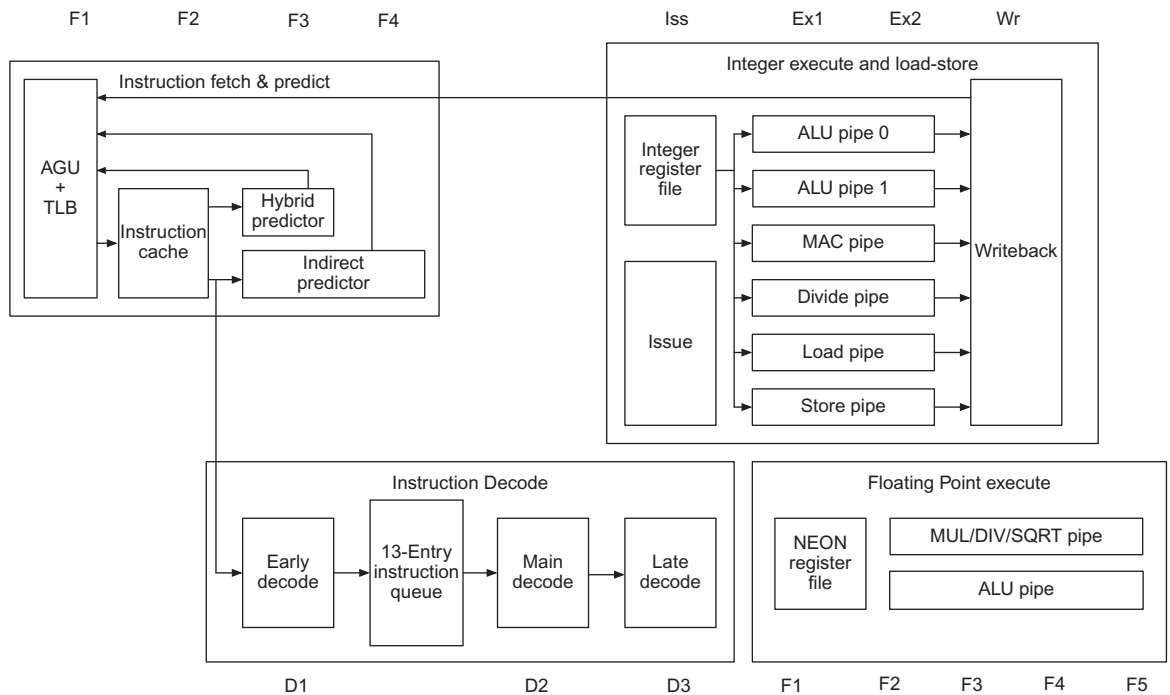

Figure 3.34 The basic structure of the A53 integer pipeline is 8 stages: F1 and F2 fetch the instruction, D1 and D2 do the basic decoding, and D3 decodes some more complex instructions and is overlapped with the first stage of the execution pipeline (ISS). After ISS, the Ex1, EX2, and WB stages complete the integer pipeline. Branches use four different predictors, depending on the type. The floating-point execution pipeline is 5 cycles deep, in addition to the 5 cycles needed for fetch and decode, yielding 10 stages in total.

The four cycles of instruction fetch include an address generation unit that produces the next PC either by incrementing the last PC or from one of four predictors:

1. A single-entry branch target cache containing two instruction cache fetches (the next two instructions following the branch, assuming the prediction is correct). This target cache is checked during the first fetch cycle, if it hits; then the next two instructions are supplied from the target cache. In case of a hit and a correct prediction, the branch is executed with no delay cycles.
2. A 3072-entry hybrid predictor, used for all instructions that do not hit in the branch target cache, and operating during F3. Branches handled by this predictor incur a 2-cycle delay.
3. A 256-entry indirect branch predictor that operates during F4; branches predicted by this predictor incur a three-cycle delay when predicted correctly.
4. An 8-deep return stack, operating during F4 and incurring a three-cycle delay.

Figure 3.35 Misprediction rate of the A53 branch predictor for SPECint2006.

Branch decisions are made in ALU pipe 0, resulting in a branch misprediction penalty of 8 cycles. [Figure 3.35](#) shows the misprediction rate for SPECint2006. The amount of work that is wasted depends on both the misprediction rate and the issue rate sustained during the time that the mispredicted branch was followed. As [Figure 3.36](#) shows, wasted work generally follows the misprediction rate, though it may be larger or occasionally shorter.

Performance of the A53 Pipeline

The A53 has an ideal CPI of 0.5 because of its dual-issue structure. Pipeline stalls can arise from three sources:

1. Functional hazards, which occur because two adjacent instructions selected for issue simultaneously use the same functional pipeline. Because the A53 is statically scheduled, the compiler should try to avoid such conflicts. When such

Figure 3.36 Wasted work due to branch misprediction on the A53. Because the A53 is an in-order machine, the amount of wasted work depends on a variety of factors, including data dependences and cache misses, both of which will cause a stall.

instructions appear sequentially, they will be serialized at the beginning of the execution pipeline, when only the first instruction will begin execution.

2. Data hazards, which are detected early in the pipeline and may stall either both instructions (if the first cannot issue, the second is always stalled) or the second of a pair. Again, the compiler should try to prevent such stalls when possible.
3. Control hazards, which arise only when branches are mispredicted.

Both TLB misses and cache misses also cause stalls. On the instruction side, a TLB or cache miss causes a delay in filling the instruction queue, likely leading to a downstream stall of the pipeline. Of course, this depends on whether it is an L1 miss, which might be largely hidden if the instruction queue was full at the time of the miss, or an L2 miss, which takes considerably longer. On the data side, a cache or TLB miss will cause the pipeline to stall because the load or store that

Figure 3.37 The estimated composition of the CPI on the ARM A53 shows that pipeline stalls are significant but are outweighed by cache misses in the poorest performing programs. This estimate is obtained by using the L1 and L2 miss rates and penalties to compute the L1 and L2 generated stalls per instruction. These are subtracted from the CPI measured by a detailed simulator to obtain the pipeline stalls. Pipeline stalls include all three hazards.

caused the miss cannot proceed down the pipeline. All other subsequent instructions will thus be stalled. Figure 3.37 shows the CPI and the estimated contributions from various sources.

The A53 uses a shallow pipeline and a reasonably aggressive branch predictor, leading to modest pipeline losses, while allowing the processor to achieve high clock rates at modest power consumption. In comparison with the i7, the A53 consumes approximately 1/200 the power for a quad core processor!

The Intel Core i7

The i7 uses an aggressive out-of-order speculative microarchitecture with deep pipelines with the goal of achieving high instruction throughput by combining multiple issue and high clock rates. The first i7 processor was introduced in 2008; the i7 6700 is the sixth generation. The basic structure of the i7 is similar, but successive

generations have enhanced performance by changing cache strategies (e.g., the aggressiveness of prefetching), increasing memory bandwidth, expanding the number of instructions in flight, enhancing branch prediction, and improving graphics support. The early i7 microarchitectures used reservations stations and reorder buffers for their out-of-order, speculative pipeline. Later microarchitectures, including the i7 6700, use register renaming, with the reservations stations acting as functional unit queues and the reorder buffer simply tracking control information.

Figure 3.38 shows the overall structure of the i7 pipeline. We will examine the pipeline by starting with instruction fetch and continuing on to instruction commit, following steps labeled in the figure.

1. **Instruction fetch**—The processor uses a sophisticated multilevel branch predictor to achieve a balance between speed and prediction accuracy. There is also a return address stack to speed up function return. Mispredictions cause a penalty of about 17 cycles. Using the predicted address, the instruction fetch unit fetches 16 bytes from the instruction cache.
2. **The 16 bytes are placed in the predecode instruction buffer**—In this step, a process called *macro-op fusion* is executed. *Macro-op fusion* takes instruction combinations such as compare followed by a branch and fuses them into a single operation, which can issue and dispatch as one instruction. Only certain special cases can be fused, since we must know that the only use of the first result is by the second instruction (i.e., compare and branch). In a study of the Intel Core architecture (which has many fewer buffers), Bird et al. (2007) discovered that macrofusion had a significant impact on the performance of integer programs resulting in an 8%–10% average increase in performance with a few programs showing negative results. There was little impact on FP programs; in fact, about half of the SPEC FP benchmarks showed negative results from macro-op fusion. The predecode stage also breaks the 16 bytes into individual x86 instructions. This predecode is nontrivial because the length of an x86 instruction can be from 1 to 17 bytes and the predecoder must look through a number of bytes before it knows the instruction length. Individual x86 instructions (including some fused instructions) are placed into the instruction queue.
3. **Micro-op decode**—Individual x86 instructions are translated into micro-ops. Micro-ops are simple RISC-V-like instructions that can be executed directly by the pipeline; this approach of translating the x86 instruction set into simple operations that are more easily pipelined was introduced in the Pentium Pro in 1997 and has been used since. Three of the decoders handle x86 instructions that translate directly into one micro-op. For x86 instructions that have more complex semantics, there is a microcode engine that is used to produce the micro-op sequence; it can produce up to four micro-ops every cycle and continues until the necessary micro-op sequence has been generated. The micro-ops are placed according to the order of the x86 instructions in the 64-entry micro-op buffer.

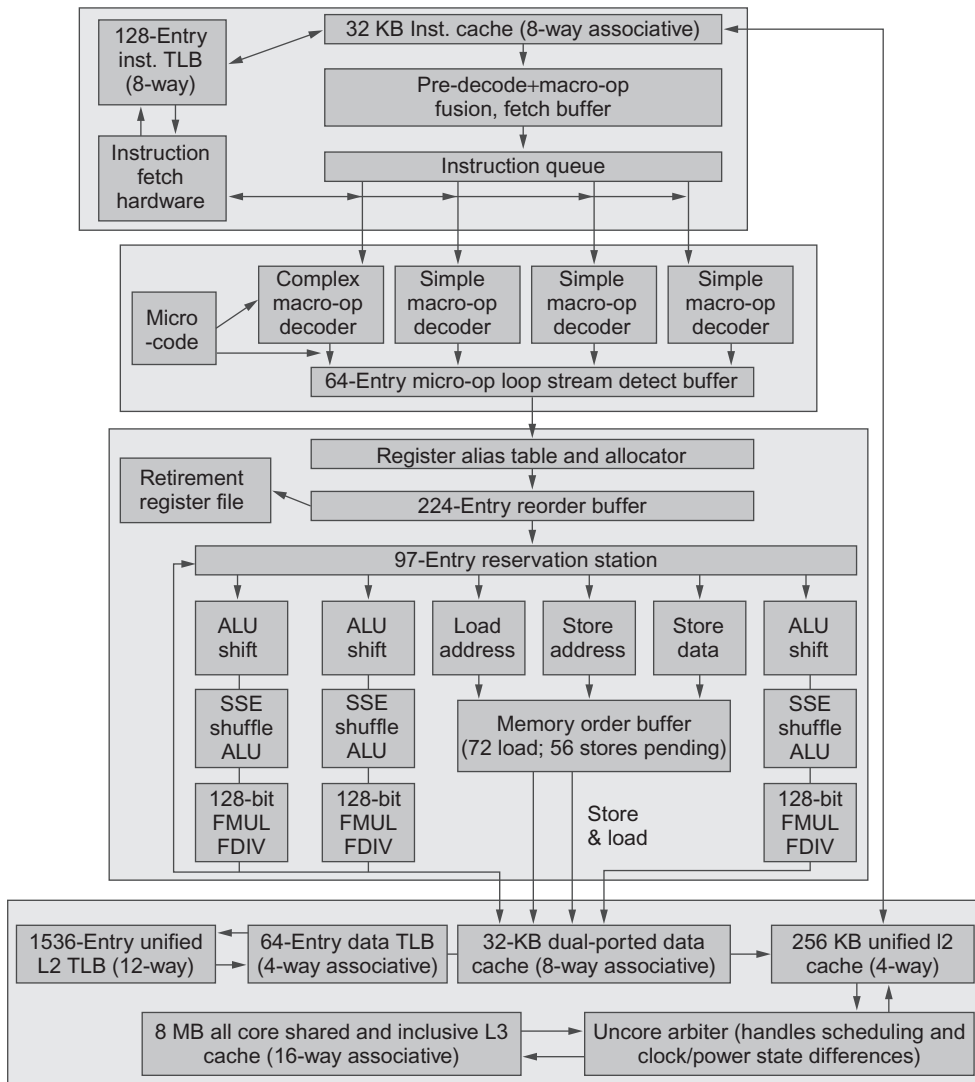

Figure 3.38 The Intel Core i7 pipeline structure shown with the memory system components. The total pipeline depth is 14 stages, with branch mispredictions typically costing 17 cycles, with the extra few cycles likely due to the time to reset the branch predictor. The six independent functional units can each begin execution of a ready micro-op in the same cycle. Up to four micro-ops can be processed in the register renaming table.

4. The micro-op buffer preforms *loop stream detection* and *microfusion*—If there is a small sequence of instructions (less than 64 instructions) that comprises a loop, the loop stream detector will find the loop and directly issue the micro-ops from the buffer, eliminating the need for the instruction fetch and instruction decode stages to be activated. Microfusion combines

instruction pairs such as ALU operation and a dependent store and issues them to a single reservation station (where they can still issue independently), thus increasing the usage of the buffer. Micro-op fusion produces smaller gains for integer programs and larger ones for FP, but the results vary widely. The different results for integer and FP programs with macro and micro fusion, probably arise from the patterns recognized and fused and the frequency of occurrence in integer versus FP programs. In the i7, which has a much larger number of reorder buffer entries, the benefits from both techniques are likely to be smaller.

5. Perform the basic instruction issue—Looking up the register location in the register tables, renaming the registers, allocating a reorder buffer entry, and fetching any results from the registers or reorder buffer before sending the micro-ops to the reservation stations. Up to four micro-ops can be processed every clock cycle; they are assigned the next available reorder buffer entries.
6. The i7 uses a centralized reservation station shared by six functional units. Up to six micro-ops may be dispatched to the functional units every clock cycle.
7. Micro-ops are executed by the individual function units, and then results are sent back to any waiting reservation station as well as to the register retirement unit, where they will update the register state once it is known that the instruction is no longer speculative. The entry corresponding to the instruction in the reorder buffer is marked as complete.
8. When one or more instructions at the head of the reorder buffer have been marked as complete, the pending writes in the register retirement unit are executed, and the instructions are removed from the reorder buffer.

In addition to the changes in the branch predictor, the major changes between the first generation i7 (the 920, Nehalem microarchitecture) and the sixth generation (i7 6700, Skylake microarchitecture) are in the sizes of the various buffers, renaming registers, and resources so as to allow many more outstanding instructions. [Figure 3.39](#) summarizes these differences.

Performance of the i7

In earlier sections, we examined the performance of the i7's branch predictor and also the performance of SMT. In this section, we look at single-thread pipeline performance. Because of the presence of aggressive speculation as well as non-blocking caches, it is difficult to accurately attribute the gap between idealized performance and actual performance. The extensive queues and buffers on the 6700 reduce the probability of stalls because of a lack of reservation stations, renaming registers, or reorder buffers significantly. Indeed, even on the earlier i7 920 with notably fewer buffers, only about 3% of the loads were delayed because no reservation station was available.

Resource	i7 920 (Nehalem)	i7 6700 (Skylake)
Micro-op queue (per thread)	28	64
Reservation stations	36	97
Integer registers	NA	180
FP registers	NA	168
Outstanding load buffer	48	72
Outstanding store buffer	32	56
Reorder buffer	128	256

Figure 3.39 The buffers and queues in the first generation i7 and the latest generation i7. Nehalem used a reservation station plus reorder buffer organization. In later microarchitectures, the reservation stations serve as scheduling resources, and register renaming is used rather than the reorder buffer; the reorder buffer in the Skylake microarchitecture serves only to buffer control information. The choices of the size of various buffers and renaming registers, while appearing sometimes arbitrary, are likely based on extensive simulation.

Thus most losses come either from branch mispredicts or cache misses. The cost of a branch mispredict is 17 cycles, whereas the cost of an L1 miss is about 10 cycles. An L2 miss is slightly more than three times as costly as an L1 miss, and an L3 miss costs about 13 times what an L1 miss costs (130–135 cycles). Although the processor will attempt to find alternative instructions to execute during L2 and L3 misses, it is likely that some of the buffers will fill before a miss completes, causing the processor to stop issuing instructions.

Figure 3.40 shows the overall CPI for the 19 SPEC CPUint2006 benchmarks compared to the CPI for the earlier i7 920. The average CPI on the i7 6700 is 0.71, whereas it is almost 1.5 times better on the i7 920, at 1.06. This difference derives from improved branch prediction and a reduction in the demand miss rates (see Figure 2.26 on page 135).

To understand how the 6700 achieves the significant improvement in CPI, let's look at the benchmarks that achieve the largest improvement. Figure 3.41 shows the five benchmarks that have a CPI ratio on the 920 that is at least 1.5 times higher than that of the 6700. Interestingly, three other benchmarks show a significant improvement in branch prediction accuracy (1.5 or more); however, those three benchmarks (HMMER, LIBQUANTUM, and SJENG) show equal or slightly higher L1 demand miss rates on the i7 6700. These misses likely arise because the aggressive prefetching is replacing cache blocks that are actually used. This type of behavior reminds designers of the challenges of maximizing performance in complex speculative multiple issue processors: rarely can significant performance be achieved by tuning only one part of the microarchitecture!

Figure 3.40 The CPI for the SPECint2006 benchmarks on the i7 6700 and the i7 920. The data in this section were collected by Professor Lu Peng and PhD student Qun Liu, both of Louisiana State University.

Benchmark	CPI ratio (920/6700)	Branch mispredict ratio (920/6700)	L1 demand miss ratio (920/6700)
ASTAR	1.51	1.53	2.14
GCC	1.82	2.54	1.82
MCF	1.85	1.27	1.71
OMNETPP	1.55	1.48	1.96
PERLBENCH	1.70	2.11	1.78

Figure 3.41 An analysis of the five integer benchmarks with the largest performance gap between the i7 6700 and 920. These five benchmarks show an improvement in the branch prediction rate and a reduction in the L1 demand miss rate.

3.13

Fallacies and Pitfalls

Our few fallacies focus on the difficulty of predicting performance and energy efficiency and extrapolating from single measures such as clock rate or CPI. We also show that different architectural approaches can have radically different behaviors for different benchmarks.

Fallacy *It is easy to predict the performance and energy efficiency of two different versions of the same instruction set architecture, if we hold the technology constant.*

Intel offers a processor for the low-end Netbook and PMD space called the Atom 230, which implements both the 64-bit and 32-bit versions of the x86 architecture. The Atom is a statically scheduled, 2-issue superscalar, quite similar in its microarchitecture to the ARM A8, a single-core predecessor of the A53. Interestingly, both the Atom 230 and the Core i7 920 have been fabricated in the same 45 nm Intel technology. [Figure 3.42](#) summarizes the Intel Core i7 920, the ARM Cortex-A8, and the Intel Atom 230. These similarities provide a rare opportunity to directly compare two radically different microarchitectures for the same instruction set while holding constant the underlying fabrication technology. Before we do the comparison, we need to say a little more about the Atom 230.

The Atom processors implement the x86 architecture using the standard technique of translating x86 instructions into RISC-like instructions (as every x86 implementation since the mid-1990s has done). Atom uses a slightly more powerful microoperation, which allows an arithmetic operation to be paired with a load or a store; this capability was added to later i7s by the use of macrofusion. This means that on average for a typical instruction mix, only 4% of the instructions require more than one microoperation. The microoperations are then executed in a 16-deep pipeline capable of issuing two instructions per clock, in order, as in the ARM A8. There are dual-integer ALUs, separate pipelines for FP add and other FP operations, and two memory operation pipelines, supporting more general dual execution than the ARM A8 but still limited by the in-order issue capability. The Atom 230 has a 32 KiB instruction cache and a 24 KiB data cache, both backed by a shared 512 KiB L2 on the same die. (The Atom 230 also supports multithreading with two threads, but we will consider only single-threaded comparisons.)

We might expect that these two processors, implemented in the same technology and with the same instruction set, would exhibit predictable behavior, in terms of relative performance and energy consumption, meaning that power and performance would scale close to linearly. We examine this hypothesis using three sets of benchmarks. The first set is a group of Java single-threaded benchmarks that come from the DaCapo benchmarks and the SPEC JVM98 benchmarks (see [Esmaeilzadeh et al. \(2011\)](#) for a discussion of the benchmarks and measurements). The second and third sets of benchmarks are from SPEC CPU2006 and consist of the integer and FP benchmarks, respectively.

Area	Specific characteristic	Intel i7 920	ARM A8	Intel Atom 230
		Four cores, each with FP	One core, no FP	One core, with FP
Physical chip properties	Clock rate	2.66 GHz	1 GHz	1.66 GHz
	Thermal design power	130 W	2 W	4 W
	Package	1366-pin BGA	522-pin BGA	437-pin BGA
	TLB	Two-level All four-way set associative 128 I/64 D	One-level fully associative 32 I/32 D	Two-level All four-way set associative 16 I/16 D
		512 L2		64 L2
	Caches	Three-level 32 KiB/32 KiB 256 KiB	Two-level 16/16 or 32/32 KiB	Two-level 32/24 KiB
		2–8 MiB	128 KiB–1 MiB	512 KiB
Memory system	Peak memory BW	17 GB/s	12 GB/sec	8 GB/s
	Peak issue rate	4 ops/clock with fusion	2 ops/clock	2 ops/clock
	Pipe line scheduling	Speculating out of order	In-order dynamic issue	In-order dynamic issue
	Branch prediction	Two-level	Two-level 512-entry BTB 4 K global history	Two-level
			8-entry return stack	

Figure 3.42 An overview of the four-core Intel i7 920, an example of a typical ARM A8 processor chip (with a 256 MiB L2, 32 KiB L1s, and no floating point), and the Intel ARM 230, clearly showing the difference in design philosophy between a processor intended for the PMD (in the case of ARM) or netbook space (in the case of Atom) and a processor for use in servers and high-end desktops. Remember, the i7 includes four cores, each of which is higher in performance than the one-core A8 or Atom. All these processors are implemented in a comparable 45 nm technology.

As we can see in [Figure 3.43](#), the i7 significantly outperforms the Atom. All benchmarks are at least four times faster on the i7, two SPECFP benchmarks are over 10 times faster, and one SPECINT benchmark runs over eight times faster! Because the ratio of clock rates of these two processors is 1.6, most of the advantage comes from a much lower CPI for the i7 920: a factor of 2.8 for the Java benchmarks, a factor of 3.1 for the SPECINT benchmarks, and a factor of 4.3 for the SPECFP benchmarks.

But the average power consumption for the i7 920 is just under 43 W, while the average power consumption of the Atom is 4.2 W, or about one-tenth of the power! Combining the performance and power leads to an energy efficiency advantage for the Atom that is typically more than 1.5 times better and often 2 times better! This comparison of two processors using the same underlying technology makes it clear that the performance advantages of an aggressive

Figure 3.43 The relative performance and energy efficiency for a set of single-threaded benchmarks shows the i7 920 is 4 to over 10 times faster than the Atom 230 but that it is about 2 times *less* power-efficient on average! Performance is shown in the columns as i7 relative to Atom, which is execution time (i7)/execution time (Atom). Energy is shown with the line as Energy (Atom)/Energy (i7). The i7 never beats the Atom in energy efficiency, although it is essentially as good on four benchmarks, three of which are floating point. The data shown here were collected by [Esmaeilzadeh et al. \(2011\)](#). The SPEC benchmarks were compiled with optimization using the standard Intel compiler, while the Java benchmarks use the Sun (Oracle) Hotspot Java VM. Only one core is active on the i7, and the rest are in deep power saving mode. Turbo Boost is used on the i7, which increases its performance advantage but slightly decreases its relative energy efficiency.

superscalar with dynamic scheduling and speculation come with a *significant disadvantage* in energy efficiency.

Fallacy *Processors with lower CPIs will always be faster.*

Fallacy *Processors with faster clock rates will always be faster.*

The key is that it is the product of CPI and clock rate that determines performance. A high clock rate obtained by deeply pipelining the processor must maintain a low CPI to get the full benefit of the faster clock. Similarly, a simple processor with a high clock rate but a low CPI may be slower.

As we saw in the previous fallacy, performance and energy efficiency can diverge significantly among processors designed for different environments even when they have the same ISA. In fact, large differences in performance can show up even within a family of processors from the same company all designed for high-end applications. Figure 3.44 shows the integer and FP performance of two different implementations of the x86 architecture from Intel, as well as a version of the Itanium architecture, also by Intel.

The Pentium 4 was the most aggressively pipelined processor ever built by Intel. It used a pipeline with over 20 stages, had seven functional units, and cached micro-ops rather than x86 instructions. Its relatively inferior performance, given the aggressive implementation, was a clear indication that the attempt to exploit more ILP (there could easily be 50 instructions in flight) had failed. The Pentium's power consumption was similar to the i7, although its transistor count was lower, as its primary caches were half as large as the i7, and it included only a 2 MiB secondary cache with no tertiary cache.

The Intel Itanium is a VLIW-style architecture, which despite the potential decrease in complexity compared to dynamically scheduled superscalars, never attained competitive clock rates with the mainline x86 processors (although it appears to achieve an overall CPI similar to that of the i7). In examining these results, the reader should be aware that they use different implementation technologies, giving the i7 an advantage in terms of transistor speed and hence clock rate for an equivalently pipelined processor. Nonetheless, the wide variation in

Processor	Implementation technology	Clock rate	Power	SPECCInt2006 base	SPECCFP2006 baseline
Intel Pentium 4 670	90 nm	3.8 GHz	115 W	11.5	12.2
Intel Itanium 2	90 nm	1.66 GHz	104 W approx. 70 W one core	14.5	17.3
Intel i7 920	45 nm	3.3 GHz	130 W total approx. 80 W one core	35.5	38.4

Figure 3.44 Three different Intel processors vary widely. Although the Itanium processor has two cores and the i7 four, only one core is used in the benchmarks; the Power column is the thermal design power with estimates for only one core active in the multicore cases.

performance—more than three times between the Pentium and i7—is astonishing. The next pitfall explains where a significant amount of this advantage comes from.

Pitfall *Sometimes bigger and dumber is better.*

Much of the attention in the early 2000s went to building aggressive processors to exploit ILP, including the Pentium 4 architecture, which used the deepest pipeline ever seen in a microprocessor, and the Intel Itanium, which had the highest peak issue rate per clock ever seen. What quickly became clear was that the main limitation in exploiting ILP often turned out to be the memory system. Although speculative out-of-order pipelines were fairly good at hiding a significant fraction of the 10- to 15-cycle miss penalties for a first-level miss, they could do very little to hide the penalties for a second-level miss that, when going to main memory, were likely to be 50–100 clock cycles.

The result was that these designs never came close to achieving the peak instruction throughput despite the large transistor counts and extremely sophisticated and clever techniques. [Section 3.15](#) discusses this dilemma and the turning away from more aggressive ILP schemes to multicore, but there was another change that exemplified this pitfall. Instead of trying to hide even more memory latency with ILP, designers simply used the transistors to build much larger caches. Both the Itanium 2 and the i7 use three-level caches compared to the two-level cache of the Pentium 4, and the third-level caches are 9 and 8 MiB compared to the 2 MiB second-level cache of the Pentium 4. Needless to say, building larger caches is a lot easier than designing the 20+-stage Pentium 4 pipeline, and based on the data in [Figure 3.44](#), doing so seems to be more effective.

Pitfall *And sometimes smarter is better than bigger and dumber.*

One of the more surprising results of the past decade has been in branch prediction. The emergence of hybrid tagged predictors has shown that a more sophisticated predictor can outperform the simple gshare predictor with the same number of bits (see [Figure 3.8](#) on page 171). One reason this result is so surprising is that the tagged predictor actually stores fewer predictions, because it also consumes bits to store tags, whereas gshare has only a large array of predictions. Nonetheless, it appears that the advantage gained by not misusing a prediction for one branch on another branch more than justifies the allocation of bits to tags versus predictions.

Pitfall *Believing that there are large amounts of ILP available, if only we had the right techniques.*

The attempts to exploit large amounts of ILP failed for several reasons, but one of the most important ones, which some designers did not initially accept, is that it is hard to find large amounts of ILP in conventionally structured programs, even with speculation. A famous study by David Wall in 1993 (see [Wall, 1993](#)) analyzed the amount of ILP available under a variety of idealistic conditions. We summarize his results for a processor configuration with roughly five to ten times the capability of the most advanced processors in 2017. Wall's study extensively documented a variety of different approaches,

and the reader interested in the challenge of exploiting ILP should read the complete study.

The aggressive processor we consider has the following characteristics:

1. Up to 64 instruction issues and dispatches per clock with *no* issue restrictions, or 8 times the total issue width of the widest processor in 2016 (the IBM Power8) and with up to 32 times as many loads and stores allowed per clock! As we have discussed, there are serious complexity and power problems with large issue rates.
2. A tournament predictor with 1K entries and a 16-entry function return predictor. This predictor is comparable to the best predictors in 2016; the predictor is not a primary bottleneck. Mispredictions are handled in one cycle, but they limit the ability to speculate.
3. Perfect disambiguation of memory references done dynamically—this is ambitious but perhaps attainable for small window sizes.
4. Register renaming with 64 additional integer and 64 additional FP registers, which is somewhat less than the most aggressive processor in 2011. Because the study assumes a latency of only one cycle for all instructions (versus 15 or more on processors like the i7 or Power8), the effective number of rename registers is about five times larger than either of those processors.

Figure 3.45 shows the result for this configuration as we vary the window size. This configuration is more complex and expensive than existing implementations, especially in terms of the number of instruction issues. Nonetheless, it gives a useful upper limit on what future implementations might yield. The data in these figures are likely to be very optimistic for another reason. There are no issue restrictions among the 64 instructions: for example, they may all be memory references. No one would even contemplate this capability in a processor for the near future. In addition, remember that in interpreting these results, cache misses and non-unit latencies were not taken into account, and both these effects have significant impacts.

The most startling observation in Figure 3.45 is that with the preceding realistic processor constraints, the effect of the window size for the integer programs is not as severe as for FP programs. This result points to the key difference between these two types of programs. The availability of loop-level parallelism in two of the FP programs means that the amount of ILP that can be exploited is higher, but for integer programs other factors—such as branch prediction, register renaming, and less parallelism, to start with—are all important limitations. This observation is critical because most of the market growth in the past decade—transaction processing, web servers, and the like—depended on integer performance, rather than floating point.

Wall's study was not believed by some, but 10 years later, the reality had sunk in, and the combination of modest performance increases with significant hardware resources and major energy issues coming from incorrect speculation forced a change in direction. We will return to this discussion in our concluding remarks.

Figure 3.45 The amount of parallelism available versus the window size for a variety of integer and floating-point programs with up to 64 arbitrary instruction issues per clock. Although there are fewer renaming registers than the window size, the fact that all operations have 1-cycle latency and that the number of renaming registers equals the issue width allows the processor to exploit parallelism within the entire window.

3.14

Concluding Remarks: What's Ahead?

As 2000 began the focus on exploiting instruction-level parallelism was at its peak. In the first five years of the new century, it became clear that the ILP approach had likely peaked and that new approaches would be needed. By 2005 Intel and all the other major processor manufacturers had revamped their approach to focus on multicore. Higher performance would be achieved through thread-level parallelism rather than instruction-level parallelism, and the responsibility for using the

processor efficiently would largely shift from the hardware to the software and the programmer. This change was the most significant change in processor architecture since the early days of pipelining and instruction-level parallelism some 25+ years earlier.

During the same period, designers began to explore the use of more data-level parallelism as another approach to obtaining performance. SIMD extensions enabled desktop and server microprocessors to achieve moderate performance increases for graphics and similar functions. More importantly, graphics processing units (GPUs) pursued aggressive use of SIMD, achieving significant performance advantages for applications with extensive data-level parallelism. For scientific applications, such approaches represent a viable alternative to the more general, but less efficient, thread-level parallelism exploited in multicores. The next chapter explores these developments in the use of data-level parallelism.

Many researchers predicted a major retrenchment in the use of ILP, predicting that two issue superscalar processors and larger numbers of cores would be the future. The advantages, however, of slightly higher issue rates and the ability of speculative dynamic scheduling to deal with unpredictable events, such as level-one cache misses, led to moderate ILP (typically about 4 issues/clock) being the primary building block in multicore designs. The addition of SMT and its effectiveness (both for performance and energy efficiency) further cemented the position of the moderate issue, out-of-order, speculative approaches. Indeed, even in the embedded market, the newest processors (e.g., the ARM Cortex-A9 and Cortex-A73) have introduced dynamic scheduling, speculation, and wider issues rates.

It is highly unlikely that future processors will try to increase the width of issue significantly. It is simply too inefficient from the viewpoint of silicon utilization and power efficiency. Consider the data in [Figure 3.46](#) that show the five processors in the IBM Power series. Over more than a decade, there has been a modest improvement in the ILP support in the Power processors, but the dominant portion

	Power4	Power5	Power6	Power7	Power8
Introduced	2001	2004	2007	2010	2014
Initial clock rate (GHz)	1.3	1.9	4.7	3.6	3.3 GHz
Transistor count (M)	174	276	790	1200	4200
Issues per clock	5	5	7	6	8
Functional units per core	8	8	9	12	16
SMT threads per core	0	2	2	4	8
Cores/chip	2	2	2	8	12
SMT threads per core	0	2	2	4	8
Total on-chip cache (MiB)	1.5	2	4.1	32.3	103.0

Figure 3.46 Characteristics of five generations of IBM Power processors. All except the Power6, which is static and in-order, were dynamically scheduled; all the processors support two load/store pipelines. The Power6 has the same functional units as the Power5 except for a decimal unit. Power7 and Power8 use embedded DRAM for the L3 cache. Power9 has been described briefly; it further expands the caches and supports off-chip HBM.

of the increase in transistor count (a factor of more than 10 from the Power4 to the Power8) went to increasing the caches and the number of cores per die. Even the expansion in SMT support seems to be more of a focus than is an increase in the ILP throughput: The ILP structure from Power4 to Power8 went from 5 issues to 8, from 8 functional units to 16 (but not increasing from the original 2 load/store units), whereas the SMT support went from nonexistent to 8 threads/processor. A similar trend can be observed across the six generations of i7 processors, where almost all the additional silicon has gone to supporting more cores. The next two chapters focus on approaches that exploit data-level and thread-level parallelism.

Historical Perspective and References

Section M.5 (available online) features a discussion on the development of pipelining and instruction-level parallelism. We provide numerous references for further reading and exploration of these topics. Section M.5 covers both Chapter 3 and Appendix H.

Case Studies and Exercises by Jason D. Bakos and Robert P. Colwell

Case Study: Exploring the Impact of Microarchitectural Techniques

Concepts illustrated by this case study

- Basic Instruction Scheduling, Reordering, Dispatch
- Multiple Issue and Hazards
- Register Renaming
- Out-of-Order and Speculative Execution
- Where to Spend Out-of-Order Resources

You are tasked with designing a new processor microarchitecture and you are trying to determine how best to allocate your hardware resources. Which of the hardware and software techniques you learned in Chapter 3 should you apply? You have a list of latencies for the functional units and for memory, as well as some representative code. Your boss has been somewhat vague about the performance requirements of your new design, but you know from experience that, all else being equal, faster is usually better. Start with the basics. [Figure 3.47](#) provides a sequence of instructions and list of latencies.

- 3.1 [10] <3.1, 3.2> What is the baseline performance (in cycles, per loop iteration) of the code sequence in [Figure 3.47](#) if no new instruction's execution could be

Latencies beyond single cycle		
Memory LD		+3
Memory SD		+1
Integer ADD, SUB		+0
Branches		+1
fadd.d		+2
fmul.d		+4
fdiv.d		+10

I2:	fld	f4,0(Ry)
I3:	fadd.d	f4,f0,f4
I4:	fadd.d	f10,f8,f2
I5:	fsd	f4,0(Ry)
I6:	addi	Rx,Rx,8
I7:	addi	Ry,Ry,8
I8:	sub	x20,x4,Rx
I9:	bnz	x20,Loop

Figure 3.47 Code and latencies for Exercises 3.1 through 3.6.

initiated until the previous instruction's execution had completed? Ignore front-end fetch and decode. Assume for now that execution does not stall for lack of the next instruction, but only one instruction/cycle can be issued. Assume the branch is taken, and that there is a one-cycle branch delay slot.

- 3.2 [10] <3.1, 3.2> Think about what latency numbers really mean—they indicate the number of cycles a given function requires to produce its output. If the overall pipeline stalls for the latency cycles of each functional unit, then you are at least guaranteed that any pair of back-to-back instructions (a “producer” followed by a “consumer”) will execute correctly. But not all instruction pairs have a producer/consumer relationship. Sometimes two adjacent instructions have nothing to do with each other. How many cycles would the loop body in the code sequence in [Figure 3.47](#) require if the pipeline detected true data dependences and only stalled on those, rather than blindly stalling everything just because one functional unit is busy? Show the code with `<stall>` inserted where necessary to accommodate stated latencies. (*Hint:* an instruction with latency +2 requires two `<stall>` cycles to be inserted into the code sequence.) Think of it this

way: a one-cycle instruction has latency $1 + 0$, meaning zero extra wait states. So, latency $1 + 1$ implies one stall cycle; latency $1 + N$ has N extra stall cycles.

- 3.3 [15] <3.1, 3.2> Consider a multiple-issue design. Suppose you have two execution pipelines, each capable of beginning execution of one instruction per cycle, and enough fetch/decode bandwidth in the front end so that it will not stall your execution. Assume results can be immediately forwarded from one execution unit to another, or to itself. Further assume that the only reason an execution pipeline would stall is to observe a true data dependency. Now how many cycles does the loop require?
- 3.4 [10] <3.1, 3.2> In the multiple-issue design of Exercise 3.3, you may have recognized some subtle issues. Even though the two pipelines have the exact same instruction repertoire, they are neither identical nor interchangeable, because there is an implicit ordering between them that must reflect the ordering of the instructions in the original program. If instruction $N + 1$ begins execution in Execution Pipe 1 at the same time that instruction N begins in Pipe 0, and $N + 1$ happens to require a shorter execution latency than N , then $N + 1$ will complete before N (even though program ordering would have implied otherwise). Recite at least two reasons why that could be hazardous and will require special considerations in the microarchitecture. Give an example of two instructions from the code in [Figure 3.47](#) that demonstrate this hazard.
- 3.5 [20] <3.1, 3.2> Reorder the instructions to improve performance of the code in [Figure 3.47](#). Assume the two-pipe machine in Exercise 3.3 and that the out-of-order completion issues of Exercise 3.4 have been dealt with successfully. Just worry about observing true data dependences and functional unit latencies for now. How many cycles does your reordered code take?
- 3.6 [10/10/10] <3.1, 3.2> Every cycle that does not initiate a new operation in a pipe is a lost opportunity, in the sense that your hardware is not living up to its potential.
 - a. [10] <3.1, 3.2> In your reordered code from Exercise 3.5, what fraction of all cycles, counting both pipes, were wasted (did not initiate a new op)?
 - b. [10] <3.1, 3.2> Loop unrolling is one standard compiler technique for finding more parallelism in code, in order to minimize the lost opportunities for performance. Hand-unroll two iterations of the loop in your reordered code from Exercise 3.5.
 - c. [10] <3.1, 3.2> What speedup did you obtain? (For this exercise, just color the $N + 1$ iteration's instructions green to distinguish them from the N th iteration's instructions; if you were actually unrolling the loop, you would have to reassign registers to prevent collisions between the iterations.)
- 3.7 [15] <3.4> Computers spend most of their time in loops, so multiple loop iterations are great places to speculatively find more work to keep CPU resources busy. Nothing is ever easy, though; the compiler emitted only one copy of that loop's code, so even though multiple iterations are handling distinct data, they will

appear to use the same registers. To keep multiple iterations' register usages from colliding, we rename their registers. Figure 3.48 shows example code that we would like our hardware to rename. A compiler could have simply unrolled the loop and used different registers to avoid conflicts, but if we expect our hardware to unroll the loop, it must also do the register renaming. How? Assume your hardware has a pool of temporary registers (call them T registers, and assume that there are 64 of them, $T0$ through $T63$) that it can substitute for those registers designated by the compiler. This rename hardware is indexed by the `src` (source) register designation, and the value in the table is the T register of the last destination that targeted that register. (Think of these table values as producers, and the `src` registers are the consumers; it doesn't much matter where the producer puts its result as long as its consumers can find it.) Consider the code sequence in Figure 3.48. Every time you see a destination register in the code, substitute the next available T , beginning with $T9$. Then update all the `src` registers accordingly, so that true data dependences are maintained. Show the resulting code. (Hint: see Figure 3.49.)

- 3.8 [20] <3.4> Exercise 3.7 explored simple register renaming: when the hardware register renamer sees a source register, it substitutes the destination T register of the last instruction to have targeted that source register. When the rename table sees a destination register, it substitutes the next available T for it, but superscalar designs need to handle multiple instructions per clock cycle at every stage in the machine, including the register renaming. A SimpleScalar processor would therefore look up both `src` register mappings for each instruction and allocate a new `dest` mapping per clock cycle. Superscalar processors must be able to do that as well, but they must also ensure that any `dest`-to-`src` relationships between the two concurrent instructions are handled correctly. Consider the sample code sequence in Figure 3.50. Assume that we would like to simultaneously

I2:	fadd.d	f5, f5, f2
I3:	fdiv.d	f2, f9, f0

Figure 3.50 Sample code for superscalar register renaming.

rename the first two instructions. Further assume that the next two available T registers to be used are known at the beginning of the clock cycle in which these two instructions are being renamed. Conceptually, what we want is for the first instruction to do its rename table lookups and then update the table per its destination's T register. Then the second instruction would do exactly the same thing, and any inter-instruction dependency would thereby be handled correctly. But there's not enough time to write that T register designation into the renaming table and then look it up again for the second instruction, all in the same clock cycle. That register substitution must instead be done live (in parallel with the register rename table update). [Figure 3.51](#) shows a circuit diagram, using multiplexers and comparators, that will accomplish the necessary on-the-fly register renaming. Your task is to show the cycle-by-cycle state of the rename table for every instruction of the code shown in [Figure 3.50](#). Assume the table starts out with every entry equal to its index (T0=0; T1=1, ...) ([Figure 3.51](#)).

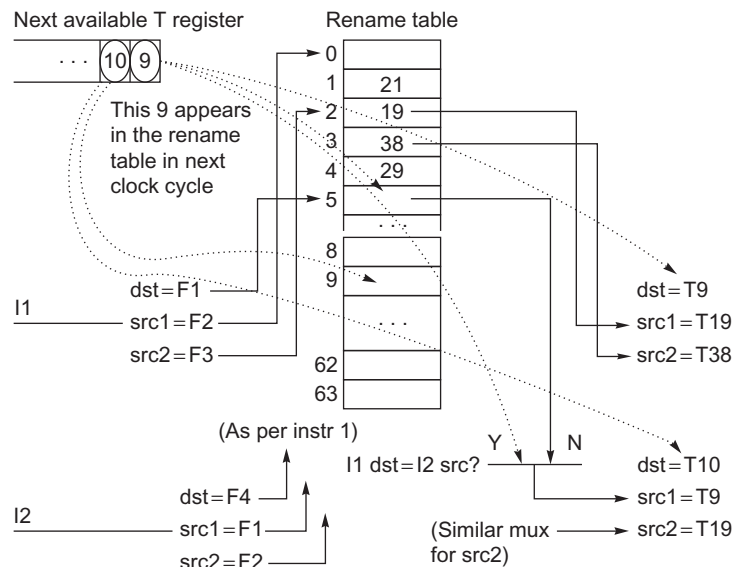

Figure 3.51 Initial state of the register renaming table.

3.9 [5] <3.4> If you ever get confused about what a register renamer has to do, go back to the assembly code you’re executing, and ask yourself what has to happen for the right result to be obtained. For example, consider a three-way superscalar machine renaming these three instructions concurrently:

```
addi x1, x1, x1
addi x1, x1, x1
addi x1, x1, x1
```

If the value of `x1` starts out as 5, what should its value be when this sequence has executed?

3.10 [20] <3.4, 3.7> Very long instruction word (VLIW) designers have a few basic choices to make regarding architectural rules for register use. Suppose a VLIW is designed with self-draining execution pipelines: once an operation is initiated, its results will appear in the destination register at most L cycles later (where L is the latency of the operation). There are never enough registers, so there is a temptation to wring maximum use out of the registers that exist. Consider Figure 3.52. If loads have a 1+2 cycle latency, unroll this loop once, and show how a VLIW capable of two loads and two adds per cycle can use the minimum number of registers, in the absence of any pipeline interruptions or stalls. Give an example of an event that, in the presence of self-draining pipelines, could disrupt this pipelining and yield wrong results.

3.11 [10/10/10] <3.3> Assume a five-stage single-pipeline microarchitecture (fetch, decode, execute, memory, write-back) and the code in Figure 3.53. All ops are one cycle except `LW` and `SW`, which are 1+2 cycles, and branches, which are 1+1 cycles. There is no forwarding. Show the phases of each instruction per clock cycle for one iteration of the loop.

- a. [10] <3.3> How many clock cycles per loop iteration are lost to branch overhead?
- b. [10] <3.3> Assume a static branch predictor, capable of recognizing a backward branch in the Decode stage. Now how many clock cycles are wasted on branch overhead?

Loop:	lw	x1,0(x2);	lw	x3,8(x2)
	<stall>			
	<stall>			
	addi	x10,x1,1;	addi	x11,x3,1
	sw	x1,0(x2);	sw	x3,8(x2)
	addi	x2,x2,8		
	sub	x4,x3,x2		
	bnz	x4,Loop		

Figure 3.52 Sample VLIW code with two adds, two loads, and two stalls.

```
Loop:      lw x1,0(x2)
           addi x1,x1, 1
           sw   x1,0(x2)
           addi x2,x2,4
           sub  x4,x3,x2
           bnz  x4,Loop
```

Figure 3.53 Code loop for Exercise 3.11.

Figure 3.54 Microarchitecture for Exercise 3.12.

- c. [10] <3.3> Assume a dynamic branch predictor. How many cycles are lost on a correct prediction?
- 3.12 [15/20/20/10/20] <3.4, 3.6> Let’s consider what dynamic scheduling might achieve here. Assume a microarchitecture as shown in Figure 3.54. Assume that the arithmetic-logical units (ALUs) can do all arithmetic ops (fmul.d, fdiv.d, fadd.d, addi, sub) and branches, and that the Reservation Station (RS) can dispatch, at most, one operation to each functional unit per cycle (one op to each ALU plus one memory op to the fld/ fsd).
 - a. [15] <3.4> Suppose all of the instructions from the sequence in Figure 3.47 are present in the RS, with no renaming having been done. Highlight any instructions in the code where register renaming would improve performance. (Hint: look for read-after-write and write-after-write hazards. Assume the same functional unit latencies as in Figure 3.47.)
 - b. [20] <3.4> Suppose the register-renamed version of the code from part (a) is resident in the RS in clock cycle *N*, with latencies as given in Figure 3.47. Show how the RS should dispatch these instructions out of order, clock by clock, to

obtain optimal performance on this code. (Assume the same RS restrictions as in part (a). Also assume that results must be written into the RS before they're available for use—no bypassing.) How many clock cycles does the code sequence take?

- c. [20] <3.4> Part (b) lets the RS try to optimally schedule these instructions. But in reality, the whole instruction sequence of interest is not usually present in the RS. Instead, various events clear the RS, and as a new code sequence streams in from the decoder, the RS must choose to dispatch what it has. Suppose that the RS is empty. In cycle 0, the first two register-renamed instructions of this sequence appear in the RS. Assume it takes one clock cycle to dispatch any op, and assume functional unit latencies are as they were for Exercise 3.2. Further assume that the front end (decoder/register-renamer) will continue to supply two new instructions per clock cycle. Show the cycle-by-cycle order of dispatch of the RS. How many clock cycles does this code sequence require now?
- d. [10] <3.4> If you wanted to improve the results of part (c), which would have helped most: (1) Another ALU? (2) Another LD/ST unit? (3) Full bypassing of ALU results to subsequent operations? or (4) Cutting the longest latency in half? What's the speedup?
- e. [20] <3.6> Now let's consider speculation, the act of fetching, decoding, and executing beyond one or more conditional branches. Our motivation to do this is twofold: the dispatch schedule we came up with in part (c) had lots of nops, and we know computers spend most of their time executing loops (which implies the branch back to the top of the loop is pretty predictable). Loops tell us where to find more work to do; our sparse dispatch schedule suggests we have opportunities to do some of that work earlier than before. In part (d) you found the critical path through the loop. Imagine folding a second copy of that path onto the schedule you got in part (b). How many more clock cycles would be required to do two loops' worth of work (assuming all instructions are resident in the RS)? (Assume all functional units are fully pipelined.)

Exercises

- 3.13 [25] <3.7, 3.8> In this exercise, you will explore performance trade-offs between three processors that each employ different types of multithreading (MT). Each of these processors is superscalar, uses in-order pipelines, requires a fixed three-cycle stall following all loads and branches, and has identical L1 caches. Instructions from the same thread issued in the same cycle are read in program order and must not contain any data or control dependences.
 - Processor A is a superscalar simultaneous MT architecture, capable of issuing up to two instructions per cycle from two threads.
 - Processor B is a fine-grained MT architecture, capable of issuing up to four instructions per cycle from a single thread and switches threads on any pipeline stall.

- Processor C is a coarse-grained MT architecture, capable of issuing up to eight instructions per cycle from a single thread and switches threads on an L1 cache miss.

Our application is a list searcher, which scans a region of memory for a specific value stored in R9 between the address range specified in R16 and R17. It is parallelized by evenly dividing the search space into four equal-sized contiguous blocks and assigning one search thread to each block (yielding four threads). Most of each thread's runtime is spent in the following unrolled loop body:

```
loop: lw x1,0(x16)
      lw x2,8(x16)
      lw x3,16(x16)
      lw x4,24(x16)
      lw x5,32(x16)
      lw x6,40(x16)
      lw x7,48(x16)
      lw x8,56(x16)
      beq x9,x1,match0
      beq x9,x2,match1
      beq x9,x3,match2
      beq x9,x4,match3
      beq x9,x5,match4
      beq x9,x6,match5
      beq x9,x7,match6
      beq x9,x8,match7
      DADDIU x16,x16,#64
      blt x16,x17,loop
```

Assume the following:

- A barrier is used to ensure that all threads begin simultaneously.
- The first L1 cache miss occurs after two iterations of the loop.
- None of the BEQAL branches is taken.
- The BLT is always taken.
- All three processors schedule threads in a round-robin fashion.

Determine how many cycles are required for each processor to complete the first two iterations of the loop.

- 3.14 [25/25/25] <3.2, 3.7> In this exercise, we look at how software techniques can extract instruction-level parallelism (ILP) in a common vector loop. The following loop is the so-called DAXPY loop (double-precision aX plus Y) and is the central operation in Gaussian elimination. The following code implements the DAXPY operation, $Y = aX + Y$, for a vector length 100. Initially, R1 is set to the base address of array X and R2 is set to the base address of Y :

```
addi    x4,x1,#800 ; x1 = upper bound for X
```

```

foo: fld      F2,0(x1)    ; (F2) = X(i)
      fmul.d   F4,F2,F0   ; (F4) = a*X(i)
      fld      F6,0(x2)   ; (F6) = Y(i)
      fadd.d   F6,F4,F6   ; (F6) = a*X(i) + Y(i)
      fsd      F6,0(x2)   ; Y(i) = a*X(i) + Y(i)
      addi     x1,x1,#8   ; increment X index
      addi     x2,x2,#8   ; increment Y index
      sltu     x3,x1,x4   ; test: continue loop?
      bnez     x3,foo     ; loop if needed

```

Assume the functional unit latencies as shown in the following table. Assume a one-cycle delayed branch that resolves in the ID stage. Assume that results are fully bypassed.

Instruction producing result	Instruction using result	Latency in clock cycles
FP multiply	FP ALU op	6
FP add	FP ALU op	4
FP multiply	FP store	5
FP add	FP store	4
Integer operations and all loads	Any	2

- a. [25] <3.2> Assume a single-issue pipeline. Show how the loop would look both unscheduled by the compiler and after compiler scheduling for both floating-point operation and branch delays, including any stalls or idle clock cycles. What is the execution time (in cycles) per element of the result vector, Y, unscheduled and scheduled? How much faster must the clock be for processor hardware alone to match the performance improvement achieved by the scheduling compiler? (Neglect any possible effects of increased clock speed on memory system performance.)
- b. [25] <3.2> Assume a single-issue pipeline. Unroll the loop as many times as necessary to schedule it without any stalls, collapsing the loop overhead instructions. How many times must the loop be unrolled? Show the instruction schedule. What is the execution time per element of the result?
- c. [25] <3.7> Assume a VLIW processor with instructions that contain five operations, as shown in Figure 3.20. We will compare two degrees of loop unrolling. First, unroll the loop 6 times to extract ILP and schedule it without any stalls (i.e., completely empty issue cycles), collapsing the loop overhead instructions, and then repeat the process but unroll the loop 10 times. Ignore the branch delay slot. Show the two schedules. What is the execution time per element of the result vector for each schedule? What percent of the operation slots are used in each schedule? How much does the size of the code differ between the two schedules? What is the total register demand for the two schedules?

- 3.15 [20/20] <3.4, 3.5, 3.7, 3.8> In this exercise, we will look at how variations on Tomasulo's algorithm perform when running the loop from Exercise 3.14. The functional units (FUs) are described in the following table.

FU type	Cycles in EX	Number of FUs	Number of reservation stations
Integer	1	1	5
FP adder	10	1	3
FP multiplier	15	1	2

Assume the following:

- Functional units are not pipelined.
 - There is no forwarding between functional units; results are communicated by the common data bus (CDB).
 - The execution stage (EX) does both the effective address calculation and the memory access for loads and stores. Thus, the pipeline is IF/ID/IS/EX/WB.
 - Loads require one clock cycle.
 - The issue (IS) and write-back (WB) result stages each require one clock cycle.
 - There are five load buffer slots and five store buffer slots.
 - Assume that the Branch on Not Equal to Zero (BNEZ) instruction requires one clock cycle.
- a. [20] <3.4–3.5> For this problem use the single-issue Tomasulo MIPS pipeline of [Figure 3.10](#) with the pipeline latencies from the preceding table. Show the number of stall cycles for each instruction and what clock cycle each instruction begins execution (i.e., enters its first EX cycle) for three iterations of the loop. How many cycles does each loop iteration take? Report your answer in the form of a table with the following column headers:
- Iteration (loop iteration number)
 - Instruction
 - Issues (cycle when instruction issues)
 - Executes (cycle when instruction executes)
 - Memory access (cycle when memory is accessed)
 - Write CDB (cycle when result is written to the CDB)
 - Comment (description of any event on which the instruction is waiting)
- Show three iterations of the loop in your table. You may ignore the first instruction.
- b. [20] <3.7, 3.8> Repeat part (a) but this time assume a two-issue Tomasulo algorithm and a fully pipelined floating-point unit (FPU).
- 3.16 [10] <3.4> Tomasulo's algorithm has a disadvantage: only one result can compute per clock per CDB. Use the hardware configuration and latencies from the previous question and find a code sequence of no more than 10 instructions where Tomasulo's algorithm must stall due to CDB contention. Indicate where this occurs in your sequence.

- 3.17 [20] <3.3> An (m,n) correlating branch predictor uses the behavior of the most recent m executed branches to choose from 2^m predictors, each of which is an n -bit predictor. A two-level local predictor works in a similar fashion, but only keeps track of the past behavior of each individual branch to predict future behavior.

There is a design trade-off involved with such predictors: correlating predictors require little memory for history, which allows them to maintain 2-bit predictors for a large number of individual branches (reducing the probability of branch instructions reusing the same predictor), while local predictors require substantially more memory to keep history and are thus limited to tracking a relatively small number of branch instructions. For this exercise, consider a (1,2) correlating predictor that can track four branches (requiring 16 bits) versus a (1,2) local predictor that can track two branches using the same amount of memory. For the following branch outcomes, provide each prediction, the table entry used to make the prediction, any updates to the table as a result of the prediction, and the final misprediction rate of each predictor. Assume that all branches up to this point have been taken. Initialize each predictor to the following:

Correlating predictor			
Entry	Branch	Last outcome	Prediction
0	0	T	T with one misprediction
1	0	NT	NT
2	1	T	NT
3	1	NT	T
4	2	T	T
5	2	NT	T
6	3	T	NT with one misprediction
7	3	NT	NT

Local predictor			
Entry	Branch	Last 2 outcomes (right is most recent)	Prediction
0	0	T,T	T with one misprediction
1	0	T,NT	NT
2	0	NT,T	NT
3	0	NT	T
4	1	T,T	T
5	1	T,NT	T with one misprediction
6	1	NT,T	NT
7	1	NT,NT	NT

Branch PC (word address)	Outcome
454	T
543	NT
777	NT
543	NT
777	NT
454	T
777	NT
454	T
543	T

- 3.18 [10] <3.9> Suppose we have a deeply pipelined processor, for which we implement a branch-target buffer for the conditional branches only. Assume that the misprediction penalty is always four cycles and the buffer miss penalty is always three cycles. Assume a 90% hit rate, 90% accuracy, and 15% branch frequency. How much faster is the processor with the branch-target buffer versus a processor that has a fixed two-cycle branch penalty? Assume a base clock cycle per instruction (CPI) without branch stalls of one.
- 3.19 [10/5] <3.9> Consider a branch-target buffer that has penalties of zero, two, and two clock cycles for correct conditional branch prediction, incorrect prediction, and a buffer miss, respectively. Consider a branch-target buffer design that distinguishes conditional and unconditional branches, storing the target address for a conditional branch and the target instruction for an unconditional branch.
- [10] <3.9> What is the penalty in clock cycles when an unconditional branch is found in the buffer?
 - [10] <3.9> Determine the improvement from branch folding for unconditional branches. Assume a 90% hit rate, an unconditional branch frequency of 5%, and a two-cycle penalty for a buffer miss. How much improvement is gained by this enhancement? How high must the hit rate be for this enhancement to provide a performance gain?

Data-Level Parallelism in Vector, SIMD, and GPU Architectures

We call these algorithms *data parallel* algorithms because their parallelism comes from simultaneous operations across large sets of data rather than from multiple threads of control.

W. Daniel Hillis and Guy L. Steele,

“Data parallel algorithms,” *Commun. ACM* (1986)

If you were plowing a field, which would you rather use: two strong oxen or 1024 chickens?

Seymour Cray, Father of the Supercomputer

(*arguing for two powerful vector processors
versus many simple processors*)

4.1

Introduction

A question for the single instruction multiple data (SIMD) architecture, which [Chapter 1](#) introduced, has always been just how wide a set of applications has significant data-level parallelism (DLP). Five years after the SIMD classification was proposed (Flynn, 1966), the answer is not only the matrix-oriented computations of scientific computing but also the media-oriented image and sound processing and machine learning algorithms, as we will see in [Chapter 7](#). Since a multiple instruction multiple data (MIMD) architecture needs to fetch one instruction per data operation, single instruction multiple data (SIMD) is potentially more energy-efficient since a single instruction can launch many data operations. These two answers make SIMD attractive for personal mobile devices as well as for servers. Finally, perhaps the biggest advantage of SIMD versus MIMD is that the programmer continues to think sequentially yet achieves parallel speedup by having parallel data operations.

This chapter covers three variations of SIMD: vector architectures, multimedia SIMD instruction set extensions, and graphics processing units (GPUs).¹

The first variation, which predates the other two by more than 30 years, extends pipelined execution of many data operations. These *vector architectures* are easier to understand and to compile to than other SIMD variations, but they were considered too expensive for microprocessors until recently. Part of that expense was in transistors, and part was in the cost of sufficient dynamic random access memory (DRAM) bandwidth, given the widespread reliance on caches to meet memory performance demands on conventional microprocessors.

The second SIMD variation borrows from the SIMD name to mean basically simultaneous parallel data operations and is now found in most instruction set architectures that support multimedia applications. For x86 architectures, the SIMD instruction extensions started with the MMX (multimedia extensions) in 1996, which were followed by several SSE (streaming SIMD extensions) versions in the next decade, and they continue until this day with AVX (advanced vector extensions). To get the highest computation rate from an x86 computer, you often need to use these SIMD instructions, especially for floating-point programs.

The third variation on SIMD comes from the graphics accelerator community, offering higher potential performance than is found in traditional multicore computers today. Although GPUs share features with vector architectures, they have their own distinguishing characteristics, in part because of the ecosystem in which they evolved. This environment has a system processor and system memory in addition to the GPU and its graphics memory. In fact, to recognize those distinctions, the GPU community refers to this type of architecture as *heterogeneous*.

¹ This chapter is based on material in Appendix F, “Vector Processors,” by Krste Asanovic, and Appendix G, “Hardware and Software for VLIW and EPIC” from the 5th edition of this book; on material in Appendix A, “Graphics and Computing GPUs,” by John Nickolls and David Kirk, from the 5th edition of *Computer Organization and Design*; and to a lesser extent on material in “Embracing and Extending 20th-Century Instruction Set Architectures,” by Joe Gebis and David Patterson, *IEEE Computer*, April 2007.

For problems with lots of data parallelism, all three SIMD variations share the advantage of being easier on the programmer than classic parallel MIMD programming.

The goal of this chapter is for architects to understand why vector is more general than multimedia SIMD, as well as the similarities and differences between vector and GPU architectures. Because vector architectures are supersets of the multimedia SIMD instructions, including a better model for compilation, and because GPUs share several similarities with vector architectures, we start with vector architectures to set the foundation for the following two sections. The next section introduces vector architectures, and Appendix G goes much deeper into the subject.

4.2

Vector Architecture

The most efficient way to execute a vectorizable application is a vector processor.

Jim Smith,

International Symposium on Computer Architecture (1994)

Vector architectures grab sets of data elements scattered about memory, place them into large sequential register files, operate on data in those register files, and then disperse the results back into memory. A single instruction works on vectors of data, which results in dozens of register-register operations on independent data elements.

These large register files act as compiler-controlled buffers, both to hide memory latency and to leverage memory bandwidth. Because vector loads and stores are deeply pipelined, the program pays the long memory latency only once per vector load or store versus once per element, thus amortizing the latency over, say, 32 elements. Indeed, vector programs strive to keep the memory busy.

The power wall leads architects to value architectures that can deliver good performance without the energy and design complexity costs of highly out-of-order superscalar processors. Vector instructions are a natural match to this trend because architects can use them to increase performance of simple in-order scalar processors without greatly raising energy demands and design complexity. In practice, developers can express many of the programs that ran well on complex out-of-order designs more efficiently as data-level parallelism in the form of vector instructions, as [Kozyrakis and Patterson \(2002\)](#) showed.

RV64V Extension

We begin with a vector processor consisting of the primary components that [Figure 4.1](#) shows. It is loosely based on the 40-year-old Cray-1, which was one of the first supercomputers. At the time of the writing of this edition, the RISC-V vector instruction set extension RVV was still under development. (The vector extension by itself is called RVV, so RV64V refers to the RISC-V base instructions

Figure 4.1 The basic structure of a vector architecture, RV64V, which includes a RISC-V scalar architecture. There are also 32 vector registers, and all the functional units are vector functional units. The vector and scalar registers have a significant number of read and write ports to allow multiple simultaneous vector operations. A set of crossbar switches (*thick gray lines*) connects these ports to the inputs and outputs of the vector functional units.

plus the vector extension.) We show a subset of RV64V, trying to capture its essence in a few pages.

The primary components of the instruction set architecture of RV64V are the following:

- **Vector registers**—Each vector register holds a single vector, and RV64V has 32 of them, each 64 bits wide. The vector register file needs to provide enough ports to feed all the vector functional units. These ports will allow a high degree of overlap among vector operations to different vector registers. The read and write ports, which total at least 16 read ports and 8 write ports, are connected to the functional unit inputs or outputs by a pair of crossbar switches. One way to

increase the register file bandwidth is to compose it from multiple banks, which work well with relatively long vectors.

- *Vector functional units*—Each unit is fully pipelined in our implementation, and it can start a new operation on every clock cycle. A control unit is needed to detect hazards, both structural hazards for functional units and data hazards on register accesses. Figure 4.1 shows that we assume an implementation of RV64V has five functional units. For simplicity, we focus on the floating-point functional units in this section.
- *Vector load/store unit*—The vector memory unit loads or stores a vector to or from memory. The vector loads and stores are fully pipelined in our hypothetical RV64V implementation so that words can be moved between the vector registers and memory with a bandwidth of one word per clock cycle, after an initial latency. This unit would also normally handle scalar loads and stores.
- *A set of scalar registers*—Scalar registers can likewise provide data as input to the vector functional units, as well as compute addresses to pass to the vector load/store unit. These are the normal 31 general-purpose registers and 32 floating-point registers of RV64G. One input of the vector functional units latches scalar values as they are read out of the scalar register file.

Figure 4.2 lists the RV64V vector instructions we use in this section. The description in Figure 4.2 assumes that the input operands are all vector registers, but there are also versions of these instructions where an operand can be a scalar register (*xi* or *fi*). RV64V uses the suffix *.vv* when both are vectors, *.vs* when the second operand is a scalar, and *.sv* when the first is a scalar register. Thus these three are all valid RV64V instructions: *vsub.vv*, *vsub.vs*, and *vsub.sv*. (Add and other commutative operations have only the first two versions, as *vadd.sv* and *vadd.vs* would be redundant.) Because the operands determine the version of the instruction, we usually let the assembler supply the appropriate suffix. The vector functional unit gets a copy of the scalar value at instruction issue time.

Although the traditional vector architectures didn't support narrow data types efficiently, vectors naturally accommodate varying data sizes (Kozyrak and Patterson, 2002). Thus, if a vector register has 32 64-bit elements, then 128×16 -bit elements, and even 256×8 -bit elements are equally valid views. Such hardware multiplicity is why a vector architecture can be useful for multimedia applications as well as for scientific applications.

Note that the RV64V instructions in Figure 4.2 omit the data type and size! An innovation of RV64V is to associate a data type and data size *with each vector register*, rather than the normal approach of the instruction supplying that information. Thus, before executing the vector instructions, a program configures the vector registers being used to specify their data type and widths. Figure 4.3 lists the options for RV64V.

Mnemonic	Name	Description
vadd	ADD	Add elements of V[rs1] and V[rs2], then put each result in V[rd]
vsub	SUBtract	Subtract elements of V[rs2] frpm V[rs1], then put each result in V[rd]
vmul	MULTiply	Multiply elements of V[rs1] and V[rs2], then put each result in V[rd]
vdiv	DIVide	Divide elements of V[rs1] by V[rs2], then put each result in V[rd]
vrem	REMAinder	Take remainder of elements of V[rs1] by V[rs2], then put each result in V[rd]
vsqrt	SQUare RooT	Take square root of elements of V[rs1], then put each result in V[rd]
vsll	Shift Left	Shift elements of V[rs1] left by V[rs2], then put each result in V[rd]
vsrl	Shift Right	Shift elements of V[rs1] right by V[rs2], then put each result in V[rd]
vsra	Shift Right Arithmetic	Shift elements of V[rs1] right by V[rs2] while extending sign bit, then put each result in V[rd]
vxor	XOR	Exclusive OR elements of V[rs1] and V[rs2], then put each result in V[rd]
vor	OR	Inclusive OR elements of V[rs1] and V[rs2], then put each result in V[rd]
vand	AND	Logical AND elements of V[rs1] and V[rs2], then put each result in V[rd]
vsgnj	SiGN source	Replace sign bits of V[rs1] with sign bits of V[rs2], then put each result in V[rd]
vsgnjn	Negative SiGN source	Replace sign bits of V[rs1] with complemented sign bits of V[rs2], then put each result in V[rd]
vsgnjx	Xor SiGN source	Replace sign bits of V[rs1] with xor of sign bits of V[rs1] and V[rs2], then put each result in V[rd]
vld	Load	Load vector register V[rd] from memory starting at address R[rs1]
vlds	Strided Load	Load V[rd] from address at R[rs1] with stride in R[rs2] (i.e., $R[rs1] + i \times R[rs2]$)
vldx	Indexed Load (Gather)	Load V[rs1] with vector whose elements are at $R[rs2] + V[rs2]$ (i.e., V[rs2] is an index)
vst	Store	Store vector register V[rd] into memory starting at address R[rs1]
vsts	Strided Store	Store V[rd] into memory at address R[rs1] with stride in R[rs2] (i.e., $R[rs1] + i \times R[rs2]$)
vstx	Indexed Store (Scatter)	Store V[rs1] into memory vector whose elements are at $R[rs2] + V[rs2]$ (i.e., V[rs2] is an index)
vpeq	Compare =	Compare elements of V[rs1] and V[rs2]. When equal, put a 1 in the corresponding 1-bit element of p[rd]; otherwise, put 0
vpne	Compare !=	Compare elements of V[rs1] and V[rs2]. When not equal, put a 1 in the corresponding 1-bit element of p[rd]; otherwise, put 0
vplt	Compare <	Compare elements of V[rs1] and V[rs2]. When less than, put a 1 in the corresponding 1-bit element of p[rd]; otherwise, put 0
vpxor	Predicate XOR	Exclusive OR 1-bit elements of p[rs1] and p[rs2], then put each result in p[rd]
vpor	Predicate OR	Inclusive OR 1-bit elements of p[rs1] and p[rs2], then put each result in p[rd]
vpand	Predicate AND	Logical AND 1-bit elements of p[rs1] and p[rs2], then put each result in p[rd]
setvl	Set Vector Length	Set vl and the destination register to the smaller of mv1 and the source register

Figure 4.2 The RV64V vector instructions. All use the R instruction format. Each vector operation with two operands is shown with both operands being vector (.vv), but there are also versions where the second operand is a scalar register (.vs) and, when it makes a difference, where the first operand is a scalar register and the second is a vector register (.sv). The type and width of the operands are determined by configuring each vector register rather than being supplied by the instruction. In addition to the vector registers and predicate registers, there are two vector control and status registers (CSRs), vl and vctype, discussed below. The strided and indexed data transfers are also explained later. Once completed, RV64 will surely have more instructions, but the ones in this figure will be included.

Integer	8, 16, 32, and 64 bits	Floating point	16, 32, and 64 bits
---------	------------------------	----------------	---------------------

Figure 4.3 Data sizes supported for RV64V assuming it also has the single- and double-precision floating-point extensions RVS and RVD. Adding RVV to such a RISC-V design means the scalar unit must also add RVH, which is a scalar instruction extension to support half-precision (16-bit) IEEE 754 floating point. Because RV32V would not have doubleword scalar operations, it could drop 64-bit integers from the vector unit. If a RISC-V implementation didn't include RVS or RVD, it could omit the vector floating-point instructions.

One reason for *dynamic register typing* is that many instructions are required for a conventional vector architecture that supports such variety. Given the combinations of data types and sizes in Figure 4.3, if not for dynamic register typing, Figure 4.2 would be several pages long!

Dynamic typing also lets programs disable unused vector registers. As a consequence, enabled vector registers are allocated all the vector memory as long vectors. For example, assume we have 1024 bytes of vector memory, if 4 vector registers are enabled and they are type 64-bit floats, the processor would give each vector register 256 bytes or $256/8=32$ elements. This value is called the maximum vector length (mvl), which is set by the processor and cannot be changed by software.

One complaint about vector architectures is that their larger state means slower context switch time. Our implementation of RV64V increases state a factor of 3: from $2 \times 32 \times 8=512$ bytes to $2 \times 32 \times 1024=1536$ bytes. A pleasant side effect of dynamic register typing is that the program can configure vector registers as *disabled* when they are not being used, so there is no need to save and restore them on a context switch.

A third benefit of dynamic register typing is that conversions between different size operands can be implicit depending on the configuration of the registers rather than as additional explicit conversion instructions. We'll see an example of this benefit in the next section.

The names `vld` and `vst` denote vector load and vector store, and they load or store an entire vectors of data. One operand is the vector register to be loaded or stored; the other operand, which is a RV64G general-purpose register, is the starting address of the vector in memory. Vector needs more registers beyond the vector registers themselves. The vector-length register `vl` is used when the natural vector length is not equal to mvl, the vector-type register `vctype` records register types, and the predicate registers `pi` are used when loops involve IF statements. We'll see them in action in the following example.

With a vector instruction, the system can perform the operations on the vector data elements in many ways, including operating on many elements simultaneously. This flexibility lets vector designs use slow but wide execution units to achieve high performance at low power. Furthermore, the independence of elements within a vector instruction set allows scaling of functional units without performing additional costly dependency checks, as superscalar processors require.

How Vector Processors Work: An Example

We can best understand a vector processor by looking at a vector loop for RV64V. Let's take a typical vector problem, which we use throughout this section:

$$Y = a \times X + Y$$

X and Y are vectors, initially resident in memory, and a is a scalar. This problem is the *SAXPY* or *DAXPY* loop that forms the inner loop of the Linpack benchmark (Dongarra et al., 2003). (*SAXPY* stands for single-precision $a \times X$ plus Y, and *DAXPY* for double precision $a \times X$ plus Y.) Linpack is a collection of linear algebra routines, and the Linpack benchmark consists of routines for performing Gaussian elimination.

For now, let us assume that the number of elements, or *length*, of a vector register (32) matches the length of the vector operation we are interested in. (This restriction will be lifted shortly.)

Example Show the code for RV64G and RV64V for the DAXPY loop. For this example, assume that X and Y have 32 elements and the starting addresses of X and Y are in $x5$ and $x6$, respectively. (A subsequent example covers when they do not have 32 elements.)

Answer Here is the RISC-V code:

```

        fld      f0,a           # Load scalar a
        addi     x28,x5,#256    # Last address to load
Loop:   fld      f1,0(x5)       # Load X[i]
        fmul.d   f1,f1,f0       # a × X[i]
        fld      f2,0(x6)       # Load Y[i]
        fadd.d   f2,f2,f1       # a × X[i] + Y[i]
        fsd      f2,0(x6)       # Store into Y[i]
        addi     x5,x5,#8        # Increment index to X
        addi     x6,x6,#8        # Increment index to Y
        bne      x28,x5,Loop     # Check if done

```

Here is the RV64V code for DAXPY:

```

vsetdcfg 4*FP64                # Enable 4 DP FP vregs
fld       f0,a                  # Load scalar a
vld       v0,x5                 # Load vector X
vmul      v1,v0,f0              # Vector-scalar mult
vld       v2,x6                 # Load vector Y
vadd      v3,v1,v2              # Vector-vector add
vst       v3,x6                 # Store the sum
vdisable                      # Disable vector regs

```

Note that the assembler determines which version of the vector operations to generate. Because the multiply has a scalar operand, it generates `vmul.v`, whereas the add doesn't, so it generates `vadd.vv`.

The initial instruction configures the first four vector registers to hold 64-bit floating-point data. The last instruction disables all vector registers. If a context switch happened after the last instruction, there is no additional state to save.

The most dramatic difference between the preceding scalar and vector code is that the vector processor greatly reduces the dynamic instruction bandwidth, executing only 8 instructions versus 258 for RV64G. This reduction occurs because the vector operations work on 32 elements and the overhead instructions that constitute nearly half the loop on RV64G are not present in the RV64V code. When the compiler produces vector instructions for such a sequence, and the resulting code spends much of its time running in vector mode, the code is said to be *vectorized* or *vectorizable*. Loops can be vectorized when they do not have dependences between iterations of a loop, which are called *loop-carried dependences* (see [Section 4.5](#)).

Another important difference between RV64G and RV64V is the frequency of pipeline interlocks for a simple implementation of RV64G. In the straightforward RV64G code, every `fadd.d` must wait for a `fmul.d`, and every `fsd` must wait for the `fadd.d`. On the vector processor, each vector instruction will stall only for the first element in each vector, and then subsequent elements will flow smoothly down the pipeline. Thus pipeline stalls are required only once per vector *instruction*, rather than once per vector *element*. Vector architects call forwarding of element-dependent operations *chaining*, in that the dependent operations are “chained” together. In this example, the pipeline stall frequency on RV64G will be about $32 \times$ higher than it is on RV64V. Software pipelining, loop unrolling (Appendix H), or out-of-order execution can reduce the pipeline stalls on RV64G; however, the large difference in instruction bandwidth cannot be reduced substantially.

Let’s show off the dynamic register typing before discussing performance of the code.

Example A common use of multiply-accumulate operations is to multiply using narrow data and to accumulate at a wider size to increase the accuracy of a sum of products. Show how the preceding code would change if `X` and `a` were single-precision instead of a double-precision floating point. Next, show the changes to this code if we switch `X`, `Y`, and `a` from floating-point type to integers.

Answer The changes are underlined in the following code. Amazingly, the same code works with two small changes: the configuration instruction includes one single-precision vector, and the scalar load is now single-precision:

```
vsetdcfg 1*FP32,3*FP64 # 1 32b, 3 64b vregs
flw      f0,a          # Load scalar a
vld      v0,x5          # Load vector X
vmul     v1,v0,f0       # Vector-scalar mult
vld      v2,x6          # Load vector Y
vadd     v3,v1,v2       # Vector-vector add
vst      v3,x6          # Store the sum
vdisable                # Disable vector regs
```

Note that RV64V hardware will implicitly perform a conversion from the narrower single-precision to the wider double-precision in this setup.

The switch to integers is almost as easy, but we must now use an integer load instruction and integer register to hold the scalar value:

<code>vsetdcfg</code>	<code>1*X32,3*X64</code>	<code># 1 32b, 3 64b int reg</code>
<code>lw</code>	<code>x7,a</code>	<code># Load scalar a</code>
<code>vld</code>	<code>v0,x5</code>	<code># Load vector X</code>
<code>vmul</code>	<code>v1,v0,x7</code>	<code># Vector-scalar mult</code>
<code>vld</code>	<code>v2,x6</code>	<code># Load vector Y</code>
<code>vadd</code>	<code>v3,v1,v2</code>	<code># Vector-vector add</code>
<code>vst</code>	<code>v3,x6</code>	<code># Store the sum</code>
<code>vdisable</code>		<code># Disable vector regs</code>

Vector Execution Time

The execution time of a sequence of vector operations primarily depends on three factors: (1) the length of the operand vectors, (2) structural hazards among the operations, and (3) the data dependences. Given the vector length and the *initiation rate*, which is the rate at which a vector unit consumes new operands and produces new results, we can compute the time for a single vector instruction.

All modern vector computers have vector functional units with multiple parallel pipelines (or *lanes*) that can produce two or more results per clock cycle, but they may also have some functional units that are not fully pipelined. For simplicity, our RV64V implementation has one lane with an initiation rate of one element per clock cycle for individual operations. Thus the execution time in clock cycles for a single vector instruction is approximately the vector length.

To simplify the discussion of vector execution and vector performance, we use the notion of a *convoy*, which is the set of vector instructions that could potentially execute together. The instructions in a convoy *must not* contain any structural hazards; if such hazards were present, the instructions would need to be serialized and initiated in different convoys. Thus the `vld` and the following `vmul` in the preceding example can be in the same convoy. As we will soon see, you can estimate performance of a section of code by counting the number of convoys. To keep this analysis simple, we assume that a convoy of instructions must complete execution before any other instructions (scalar or vector) can begin execution.

It might seem that in addition to vector instruction sequences with structural hazards, sequences with read-after-write dependency hazards should also be in separate convoys. However, chaining allows them to be in the same convoy since it allows a vector operation to start as soon as the individual elements of its vector source operand become available: the results from the first functional unit in the chain are “forwarded” to the second functional unit. In practice, we often implement chaining by allowing the processor to read and write a particular vector register at the same time, albeit to different elements. Early implementations of

chaining worked just like forwarding in scalar pipelining, but this restricted the timing of the source and destination instructions in the chain. Recent implementations use *flexible chaining*, which allows a vector instruction to chain to essentially any other active vector instruction, assuming that we don't generate a structural hazard. All modern vector architectures support flexible chaining, which we assume throughout this chapter.

To turn convoys into execution time, we need a metric to estimate the length of a convoy. It is called a *chime*, which is simply the unit of time taken to execute one convoy. Thus a vector sequence that consists of m convoys executes in m chimes; for a vector length of n , for our simple RV64V implementation, this is approximately $m \times n$ clock cycles.

The chime approximation ignores some processor-specific overheads, many of which are dependent on vector length. Therefore measuring time in chimes is a better approximation for long vectors than for short ones. We will use the chime measurement, rather than clock cycles per result, to indicate explicitly that we are ignoring certain overheads.

If we know the number of convoys in a vector sequence, we know the execution time in chimes. One source of overhead ignored in measuring chimes is any limitation on initiating multiple vector instructions in a single clock cycle. If only one vector instruction can be initiated in a clock cycle (the reality in most vector processors), the chime count will underestimate the actual execution time of a convoy. Because the length of vectors is typically much greater than the number of instructions in the convoy, we will simply assume that the convoy executes in one chime.

Example Show how the following code sequence lays out in convoys, assuming a single copy of each vector functional unit:

```

vld    v0,x5           # Load vector X
vmul   v1,v0,f0        # Vector-scalar multiply
vld    v2,x6           # Load vector Y
vadd   v3,v1,v2        # Vector-vector add
vst    v3,x6           # Store the sum

```

How many chimes will this vector sequence take? How many cycles per FLOP (floating-point operation) are needed, ignoring vector instruction issue overhead?

Answer The first convoy starts with the first `vld` instruction. The `vmul` is dependent on the first `vld`, but chaining allows it to be in the same convoy.

The second `vld` instruction must be in a separate convoy because there is a structural hazard on the load/store unit for the prior `vld` instruction. The `vadd` is dependent on the second `vld`, but it can again be in the same convoy via chaining. Finally, the `vst` has a structural hazard on the `vld` in the second convoy, so it must go in the third convoy. This analysis leads to the following layout of vector instructions into convoys:

1. `vld` `vmul`
2. `vld` `vadd`
3. `vst`

The sequence requires three convoys. Because the sequence takes three chimes and there are two floating-point operations per result, the number of cycles per FLOP is 1.5 (ignoring any vector instruction issue overhead). Note that, although we allow the `vld` and `vmul` both to execute in the first convoy, most vector machines will take 2 clock cycles to initiate the instructions.

This example shows that the chime approximation is reasonably accurate for long vectors. For example, for 32-element vectors, the time in chimes is 3, so the sequence would take about 32×3 or 96 clock cycles. The overhead of issuing convoys in two separate clock cycles would be small.

Another source of overhead is far more significant than the issue limitation. The most important source of overhead ignored by the chime model is vector *start-up time*, which is the latency in clock cycles until the pipeline is full. The start-up time is principally determined by the pipelining latency of the vector functional unit. For RV64V, we will use the same pipeline depths as the Cray-1, although latencies in more modern processors have tended to increase, especially for vector loads. All functional units are fully pipelined. The pipeline depths are 6 clock cycles for floating-point add, 7 for floating-point multiply, 20 for floating-point divide, and 12 for vector load.

Given these vector basics, the next several sections will give optimizations that either improve the performance or increase the types of programs that can run well on vector architectures. In particular, they will answer these questions:

- How can a vector processor execute a single vector faster than one element per clock cycle? Multiple elements per clock cycle improve performance.
- How does a vector processor handle programs where the vector lengths are not the same as the maximum vector length (`mv1`)? Because most application vectors don't match the architecture vector length, we need an efficient solution to this common case.
- What happens when there is an IF statement inside the code to be vectorized? More code can vectorize if we can efficiently handle conditional statements.
- What does a vector processor need from the memory system? Without sufficient memory bandwidth, vector execution can be futile.
- How does a vector processor handle multiple dimensional matrices? This popular data structure must vectorize for vector architectures to do well.
- How does a vector processor handle sparse matrices? This popular data structure must vectorize also.

- How do you program a vector computer? Architectural innovations that are a mismatch to programming languages and their compilers may not get widespread use.

The rest of this section introduces each of these optimizations of the vector architecture, and Appendix G goes into greater depth.

Multiple Lanes: Beyond One Element per Clock Cycle

A critical advantage of a vector instruction set is that it allows software to pass a large amount of parallel work to hardware using only a single short instruction. One vector instruction can include scores of independent operations yet be encoded in the same number of bits as a conventional scalar instruction. The parallel semantics of a vector instruction allow an implementation to execute these elemental operations using a deeply pipelined functional unit, as in the RV64V implementation we've studied so far; an array of parallel functional units; or a combination of parallel and pipelined functional units. [Figure 4.4](#) illustrates how to improve vector performance by using parallel pipelines to execute a vector add instruction.

The RV64V instruction set has the property that all vector arithmetic instructions only allow element N of one vector register to take part in operations with element N from other vector registers. This dramatically simplifies the design of a highly parallel vector unit, which can be structured as multiple parallel *lanes*. As with a traffic highway, we can increase the peak throughput of a vector unit by adding more lanes. [Figure 4.5](#) shows the structure of a four-lane vector unit. Thus going to four lanes from one lane reduces the number of clocks for a chime from 32 to 8. For multiple lanes to be advantageous, both the applications and the architecture must support long vectors; otherwise, they will execute so quickly that you'll run out of instruction bandwidth, requiring ILP techniques (see [Chapter 3](#)) to supply enough vector instructions.

Each lane contains one portion of the vector register file and one execution pipeline from each vector functional unit. Each vector functional unit executes vector instructions at the rate of one element group per cycle using multiple pipelines, one per lane. The first lane holds the first element (element 0) for all vector registers, and so the first element in any vector instruction will have its source and destination operands located in the first lane. This allocation allows the arithmetic pipeline local to the lane to complete the operation without communicating with other lanes. Avoiding interlane communication reduces the wiring cost and register file ports required to build a highly parallel execution unit and helps explain why vector computers can complete up to 64 operations per clock cycle (2 arithmetic units and 2 load/store units across 16 lanes).

Adding multiple lanes is a popular technique to improve vector performance as it requires little increase in control complexity and does not require changes to existing machine code. It also allows designers to trade off die area, clock rate, voltage, and energy without sacrificing peak performance. If the clock rate of a

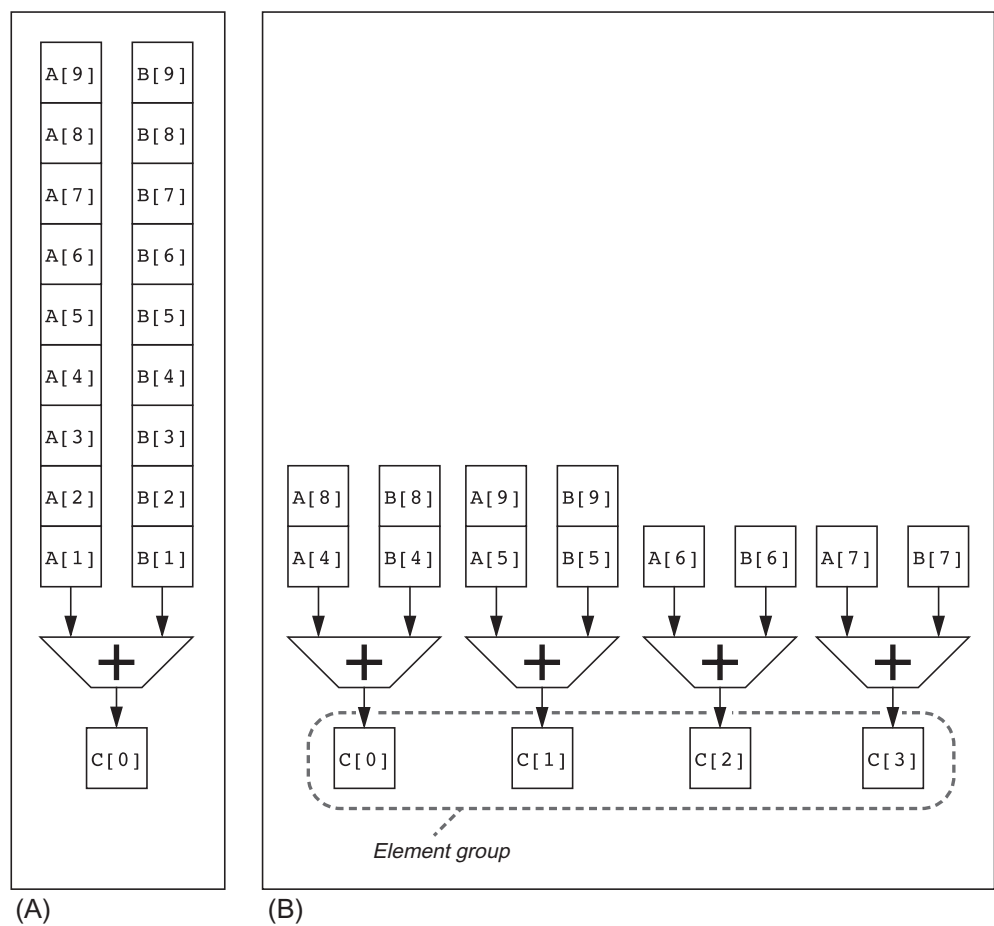

Figure 4.4 Using multiple functional units to improve the performance of a single vector add instruction, $C = A + B$. The vector processor (A) on the left has a single add pipeline and can complete one addition per clock cycle. The vector processor (B) on the right has four add pipelines and can complete four additions per clock cycle. The elements within a single vector add instruction are interleaved across the four pipelines. The set of elements that move through the pipelines together is termed an *element group*. Reproduced with permission from Asanovic, K., 1998. Vector Microprocessors (Ph.D. thesis). Computer Science Division, University of California, Berkeley.

vector processor is halved, doubling the number of lanes will retain the same peak performance.

Vector-Length Registers: Handling Loops Not Equal to 32

A vector register processor has a natural vector length determined by the maximum vector length (mvl). This length, which was 32 in our example above, is unlikely

Figure 4.5 Structure of a vector unit containing four lanes. The vector register memory is divided across the lanes, with each lane holding every fourth element of each vector register. The figure shows three vector functional units: an FP add, an FP multiply, and a load-store unit. Each of the vector arithmetic units contains four execution pipelines, one per lane, which act in concert to complete a single vector instruction. Note how each section of the vector register file needs to provide only enough ports for pipelines local to its lane. This figure does not show the path to provide the scalar operand for vector-scalar instructions, but the scalar processor (or Control Processor) broadcasts a scalar value to all lanes.

to match the real vector length in a program. Moreover, in a real program, the length of a particular vector operation is often *unknown* at compile time. In fact, a single piece of code may require different vector lengths. For example, consider this code:

```
for (i=0; i < n; i=i+1)
    Y[i] = a * X[i] + Y[i];
```

The size of all the vector operations depends on n , which may not even be known until run time. The value of n might also be a parameter to a procedure containing the preceding loop and therefore subject to change during execution.

The solution to these problems is to add a *vector-length register* (v_l). The v_l controls the length of any vector operation, including a vector load or store. The value in the v_l , however, cannot be greater than the maximum vector length (mv_l). This solves our problem as long as the real length is less than or equal to the maximum vector length (mv_l). This parameter means the length of vector registers can grow in later computer generations without changing the instruction set. As we will see in the next section, multimedia SIMD extensions have no equivalent of mv_l , so they expand the instruction set every time they increase their vector length.

What if the value of n is not known at compile time and thus may be greater than the mv_l ? To tackle the second problem where the vector is longer than the maximum length, a technique called *strip mining* is traditionally used. Strip mining is the generation of code such that each vector operation is done for a size less than or equal to the mv_l . One loop handles any number of iterations that is a multiple of the mv_l and another loop that handles any remaining iterations and must be less than the mv_l . RISC-V has a better solution than a separate loop for strip mining. The instruction `setvl` writes the smaller of the mv_l and the loop variable n into v_l (and to another register). If the number of iterations of the loop is larger than n , then the fastest the loop can compute is mv_l values at time, so `setvl` sets v_l to mv_l . If n is smaller than mv_l , it should compute only on the last n elements in this final iteration of the loop, so `setvl` sets v_l to n . `setvl` also writes another scalar register to help with later loop bookkeeping. Below is the RV64V code for vector DAXPY for any value of n .

```

vsetdcfg 2 DP FP      # Enable 2 64b Fl.Pt. registers
fld      f0,a         # Load scalar a
loop: setvl t0,a0      # vl = t0 = min(mvl,n)
vld      v0,x5        # Load vector X
slli     t1,t0,3       # t1 = vl * 8 (in bytes)
add      x5,x5,t1      # Increment pointer to X by vl*8
vmul     v0,v0,f0      # Vector-scalar mult
vld      v1,x6        # Load vector Y
vadd     v1,v0,v1      # Vector-vector add
sub      a0,a0,t0      # n -= vl (t0)
vst      v1,x6        # Store the sum into Y
add      x6,x6,t1      # Increment pointer to Y by vl*8
bnez     a0,loop       # Repeat if n != 0
vdisable                # Disable vector regs

```

Predicate Registers: Handling IF Statements in Vector Loops

From Amdahl's law, we know that the speedup on programs with low to moderate levels of vectorization will be very limited. The presence of conditionals (IF statements) inside loops and the use of sparse matrices are two main reasons for lower levels of vectorization. Programs that contain IF statements in loops cannot be run

Figure 4.6 A vector of arbitrary length processed with strip mining. All blocks but the first are of length MVL, utilizing the full power of the vector processor. In this figure, we use the variable m for the expression $(n \% MVL)$. (The C operator $\%$ is modulo.)

in vector mode using the techniques we have discussed up to now because the IF statements introduce control dependences into a loop. Likewise, we cannot implement sparse matrices efficiently using any of the capabilities we have seen so far. We examine strategies for dealing with conditional execution here, leaving the discussion of sparse matrices for later.

Consider the following loop written in C:

```
for (i = 0; i < 64; i=i+1)
    if (X[i] != 0)
        X[i] = X[i] - Y[i];
```

This loop cannot normally be vectorized because of the conditional execution of the body; however, if the inner loop could be run for the iterations for which $X[i] \neq 0$, then the subtraction could be vectorized.

The common extension for this capability is *vector-mask control*. In RV64V, predicate registers hold the mask and essentially provide conditional execution of each element operation in a vector instruction. These registers use a Boolean vector to control the execution of a vector instruction, just as conditionally executed instructions use a Boolean condition to determine whether to execute a scalar instruction (see [Chapter 3](#)). When the predicate register p0 is set, all following vector instructions operate only on the vector elements whose corresponding entries in the predicate register are 1. The entries in the destination vector register that correspond to a 0 in the mask register are unaffected by the vector operation. Like vector registers, predicate registers are configured and can be disabled. Enabling a predicate register initializes it to all 1s, meaning that subsequent vector instructions operate on all vector elements. We can now use the following code for the previous loop, assuming that the starting addresses of X and Y are in $x5$ and $x6$, respectively:

```
vsetdcfg    2*FP64    # Enable 2 64b FP vector regs
vsetpcfgi   1        # Enable 1 predicate register
vld         v0,x5     # Load vector X into v0
vld         v1,x6     # Load vector Y into v1
fmv.d.x     f0,x0     # Put (FP) zero into f0
```

```

vpne      p0,v0,f0    # Set p0(i) to 1 if v0(i)!=f0
vsub      v0,v0,v1    # Subtract under vector mask
vst       v0,x5       # Store the result in X
vdisable                      # Disable vector registers
vpdisable                      # Disable predicate registers

```

Compiler writers use the term *IF-conversion* to transform an IF statement into a straight-line code sequence using conditional execution.

Using a vector-mask register does have overhead, however. With scalar architectures, conditionally executed instructions still require execution time when the condition is not satisfied. Nonetheless, the elimination of a branch and the associated control dependences can make a conditional instruction faster even if it sometimes does useless work. Similarly, vector instructions executed with a vector mask still take the same execution time, even for the elements where the mask is zero. Likewise, despite a significant number of zeros in the mask, using vector-mask control may still be significantly faster than using scalar mode.

As we will see in [Section 4.4](#), one difference between vector processors and GPUs is the way they handle conditional statements. Vector processors make the predicate registers part of the architectural state and rely on compilers to manipulate mask registers explicitly. In contrast, GPUs get the same effect using hardware to manipulate internal mask registers that are invisible to GPU software. In both cases, the hardware spends the time to execute a vector element whether the corresponding mask bit is 0 or 1, so the GFLOPS rate drops when masks are used.

Memory Banks: Supplying Bandwidth for Vector Load/Store Units

The behavior of the load/store vector unit is significantly more complicated than that of the arithmetic functional units. The start-up time for a load is the time to get the first word from memory into a register. If the rest of the vector can be supplied without stalling, then the vector initiation rate is equal to the rate at which new words are fetched or stored. Unlike simpler functional units, the initiation rate may not necessarily be 1 clock cycle because memory bank stalls can reduce effective throughput.

Typically, penalties for start-ups on load/store units are higher than those for arithmetic units—over 100 clock cycles on many processors. For RV64V, we assume a start-up time of 12 clock cycles, the same as the Cray-1. (Recent vector computers use caches to bring down latency of vector loads and stores.)

To maintain an initiation rate of one word fetched or stored per clock cycle, the memory system must be capable of producing or accepting this much data. Spreading accesses across multiple independent memory banks usually delivers the desired rate. As we will soon see, having significant numbers of banks is useful for dealing with vector loads or stores that access rows or columns of data.

Most vector processors use memory banks, which allow several independent accesses rather than simple memory interleaving for three reasons:

1. Many vector computers support many loads or stores per clock cycle, and the memory bank cycle time is usually several times larger than the processor cycle time. To support simultaneous accesses from multiple loads or stores, the memory system needs multiple banks and needs to be able to control the addresses to the banks independently.
2. Most vector processors support the ability to load or store data words that are not sequential. In such cases, independent bank addressing, rather than interleaving, is required.
3. Most vector computers support multiple processors sharing the same memory system, so each processor will be generating its own separate stream of addresses.

In combination, these features lead to the desire for a large number of independent memory banks, as the following example shows.

Example The largest configuration of a Cray T90 (Cray T932) has 32 processors, each capable of generating 4 loads and 2 stores per clock cycle. The processor clock cycle is 2.167 ns, while the cycle time of the SRAMs used for the memory system is 15 ns. Calculate the minimum number of memory banks required to allow all processors to run at the full memory bandwidth.

Answer The maximum number of memory references each cycle is 192: 32 processors times 6 references per processor. Each SRAM bank is busy for $15/2.167 = 6.92$ clock cycles, which we round up to 7 processor clock cycles. Therefore we require a minimum of $192 \times 7 = 1344$ memory banks!

The Cray T932 actually has 1024 memory banks, so the early models could not sustain the full bandwidth to all processors simultaneously. A subsequent memory upgrade replaced the 15 ns asynchronous SRAMs with pipelined synchronous SRAMs that more than halved the memory cycle time, thereby providing sufficient bandwidth.

Taking a higher-level perspective, vector load/store units play a similar role to prefetch units in scalar processors in that both try to deliver data bandwidth by supplying processors with streams of data.

Stride: Handling Multidimensional Arrays in Vector Architectures

The position in memory of adjacent elements in a vector may not be sequential. Consider this straightforward code for matrix multiply in C:

```

for (i = 0; i < 100; i=i+1)
  for (j = 0; j < 100; j=j+1) {
    A[i][j] = 0.0;
    for (k = 0; k < 100; k=k+1)
      A[i][j] = A[i][j] + B[i][k] * D[k][j];
  }

```

We could vectorize the multiplication of each row of B with each column of D and strip-mine the inner loop with k as the index variable.

To do so, we must consider how to address adjacent elements in B and adjacent elements in D. When an array is allocated memory, it is linearized and must be laid out in either row-major order (as in C) or column-major order (as in Fortran). This linearization means that either the elements in the row or the elements in the column are not adjacent in memory. For example, the preceding C code allocates in row-major order, so the elements of D that are accessed by iterations in the inner loop are separated by the row size times 8 (the number of bytes per entry) for a total of 800 bytes. In [Chapter 2](#), we saw that blocking could improve locality in cache-based systems. For vector processors without caches, we need another technique to fetch elements of a vector that are not adjacent in memory.

This distance separating elements to be gathered into a single vector register is called the *stride*. In this example, matrix D has a stride of 100 double words (800 bytes), and matrix B would have a stride of 1 double word (8 bytes). For column-major order, which is used by Fortran, the strides would be reversed. Matrix D would have a stride of 1, or 1 double word (8 bytes), separating successive elements, while matrix B would have a stride of 100, or 100 double words (800 bytes). Thus, without reordering the loops, the compiler can't hide the long distances between successive elements for both B and D.

Once a vector is loaded into a vector register, it acts as if it had logically adjacent elements. Thus a vector processor can handle strides greater than one, called *nonunit strides*, using only vector load and vector store operations with stride capability. This ability to access nonsequential memory locations and to reshape them into a dense structure is one of the major advantages of a vector architecture.

Caches inherently deal with unit-stride data; increasing block size can help reduce miss rates for large scientific datasets with unit stride, but increasing block size can even have a negative effect for data that are accessed with nonunit strides. While blocking techniques can solve some of these problems (see [Chapter 2](#)), the ability to access noncontiguous data efficiently remains an advantage for vector processors on certain problems, as we will see in [Section 4.7](#).

On RV64V, where the addressable unit is a byte, the stride for our example would be 800. The value must be computed dynamically because the size of the matrix may not be known at compile time or—just like vector length—may change for different executions of the same statement. The vector stride, like the vector starting address, can be put in a general-purpose register. Then the RV64V instruction VLDS (load vector with stride) fetches the vector into a vector

register. Likewise, when storing a nonunit stride vector, use the instruction VSTS (store vector with stride).

Supporting strides greater than one complicates the memory system. Once we introduce nonunit strides, it becomes possible to request accesses from the same bank frequently. When multiple accesses contend for a bank, a memory bank conflict occurs, thereby stalling one access. A bank conflict and thus a stall will occur if

$$\frac{\text{Number of banks}}{\text{Least common multiple (Stride, Number of banks)}} < \text{Bank busy time}$$

Example Suppose we have 8 memory banks with a bank busy time of 6 clocks and a total memory latency of 12 cycles. How long will it take to complete a 64-element vector load with a stride of 1? With a stride of 32?

Answer Because the number of banks is larger than the bank busy time, for a stride of 1, the load will take $12 + 64 = 76$ clock cycles, or 1.2 clock cycles per element. The worst possible stride is a value that is a multiple of the number of memory banks, as in this case with a stride of 32 and 8 memory banks. Every access to memory (after the first one) will collide with the previous access and will have to wait for the 6-clock-cycle bank busy time. The total time will be $12 + 1 + 6 * 63 = 391$ clock cycles, or 6.1 clock cycles per element, slowing it down by a factor of 5!

Gather-Scatter: Handling Sparse Matrices in Vector Architectures

As previously mentioned, sparse matrices are commonplace, so it is important to have techniques to allow programs with sparse matrices to execute in vector mode. In a sparse matrix, the elements of a vector are usually stored in some compacted form and then accessed indirectly. Assuming a simplified sparse structure, we might see code that looks like this:

```
for (i = 0; i < n; i=i+1)
    A[K[i]] = A[K[i]] + C[M[i]];
```

This code implements a sparse vector sum on the arrays A and C, using index vectors K and M to designate the nonzero elements of A and C. (A and C must have the same number of nonzero elements— n of them—so K and M are the same size.)

The primary mechanism for supporting sparse matrices is *gather-scatter operations* using index vectors. The goal of such operations is to support moving between a compressed representation (i.e., zeros are not included) and normal representation (i.e., the zeros are included) of a sparse matrix. A *gather* operation takes an *index vector* and fetches the vector whose elements are at the addresses given by adding a base address to the offsets given in the index vector. The result is a dense vector in a vector register. After these elements are operated on in a dense

form, the sparse vector can be stored in an expanded form by a *scatter* store, using the same index vector. Hardware support for such operations is called *gather-scatter*, and it appears on nearly all modern vector processors. The RV64V instructions are *vldi* (load vector indexed or gather) and *vsti* (store vector indexed or scatter). For example, if *x5*, *x6*, *x7*, and *x28* contain the starting addresses of the vectors in the previous sequence, we can code the inner loop with vector instructions such as:

```

vsetdcfg  4*FP64           # 4 64b FP vector registers
vld       v0, x7           # Load K[]
vldx      v1, x5, v0)      # Load A[K[]]
vld       v2, x28          # Load M[]
vldi      v3, x6, v2)      # Load C[M[]]
vadd      v1, v1, v3        # Add them
vstx      v1, x5, v0)      # Store A[K[]]
vdisable                     # Disable vector registers

```

This technique allows code with sparse matrices to run in vector mode. A simple vectorizing compiler could not automatically vectorize the preceding source code because the compiler would not know that the elements of *K* are distinct values, and thus that no dependences exist. Instead, a programmer directive would tell the compiler that it was safe to run the loop in vector mode.

Although indexed loads and stores (gather and scatter) can be pipelined, they typically run much more slowly than nonindexed loads or stores, because the memory banks are not known from the start of the instruction. The register file must also provide communication between the lanes of a vector unit to support gather and scatter.

Each element of a gather or scatter has an individual address, so they can't be handled in groups, and there can be conflicts at many places throughout the memory system. Thus each individual access incurs significant latency even on cache-based systems. However, as [Section 4.7](#) shows, a memory system can deliver better performance by designing for this case and by using more hardware resources versus when architects have a *laissez-faire* attitude toward such unpredictable accesses.

As we will see in [Section 4.4](#), all loads are gathers and all stores are scatters in GPUs in that no separate instructions restrict addresses to be sequential. To turn the potentially slow gathers and scatters into the more efficient unit-stride accesses to memory, the GPU hardware must recognize the sequential addresses during execution and the GPU programmer to ensure that all the addresses in a gather or scatter are to adjacent locations.

Programming Vector Architectures

An advantage of vector architectures is that compilers can tell programmers at compile time whether a section of code will vectorize or not, often giving hints

Benchmark name	Operations executed in vector mode, compiler-optimized	Operations executed in vector mode, with programmer aid	Speedup from hint optimization
BDNA	96.1%	97.2%	1.52
MG3D	95.1%	94.5%	1.00
FLO52	91.5%	88.7%	N/A
ARC3D	91.1%	92.0%	1.01
SPEC77	90.3%	90.4%	1.07
MDG	87.7%	94.2%	1.49
TRFD	69.8%	73.7%	1.67
DYFESM	68.8%	65.6%	N/A
ADM	42.9%	59.6%	3.60
OCEAN	42.8%	91.2%	3.92
TRACK	14.4%	54.6%	2.52
SPICE	11.5%	79.9%	4.06
QCD	4.2%	75.1%	2.15

Figure 4.7 Level of vectorization among the Perfect Club benchmarks when executed on the Cray Y-MP (Vajapeyam, 1991). The first column shows the vectorization level obtained with the compiler without hints, and the second column shows the results after the codes have been improved with hints from a team of Cray Research programmers.

as to why it did not vectorize the code. This straightforward execution model allows experts in other domains to learn how to improve performance by revising their code or by giving hints to the compiler when it's okay to assume independence between operations, such as for gather-scatter data transfers. It is this dialogue between the compiler and the programmer, with each side giving hints to the other on how to improve performance, that simplifies programming of vector computers.

Today, the main factor that affects the success with which a program runs in vector mode is the structure of the program itself: Do the loops have true data dependences (see Section 4.5), or can they be restructured so as not to have such dependences? This factor is influenced by the algorithms chosen and, to some extent, by how they are coded.

As an indication of the level of vectorization achievable in scientific programs, let's look at the vectorization levels observed for the Perfect Club benchmarks. Figure 4.7 shows the percentage of operations executed in vector mode for two versions of the code running on the Cray Y-MP. The first version is that obtained with just compiler optimization on the original code, while the second version uses extensive hints from a team of Cray Research programmers. Several studies of the performance of applications on vector processors show a wide variation in the level of compiler vectorization.

The hint-rich versions show significant gains in vectorization level for codes that the compiler could not vectorize well by itself, with all codes now above 50% vectorization. The median vectorization improved from about 70% to about 90%.

4.3

SIMD Instruction Set Extensions for Multimedia

SIMD Multimedia Extensions started with the simple observation that many media applications operate on narrower data types than the 32-bit processors were optimized for. Graphics systems would use 8 bits to represent each of the three primary colors plus 8 bits for transparency. Depending on the application, audio samples are usually represented with 8 or 16 bits. By partitioning the carry chains within, say, a 256-bit adder, a processor could perform simultaneous operations on short vectors of thirty-two 8-bit operands, sixteen 16-bit operands, eight 32-bit operands, or four 64-bit operands. The additional cost of such partitioned adders was small. Figure 4.8 summarizes typical multimedia SIMD instructions. Like vector instructions, a SIMD instruction specifies the same operation on vectors of data. Unlike vector machines with large register files such as the RISC-V RV64V vector registers, which can hold, say, thirty-two 64-bit elements in each of 32 vector registers, SIMD instructions tend to specify fewer operands and thus use much smaller register files.

In contrast to vector architectures, which offer an elegant instruction set that is intended to be the target of a vectorizing compiler, SIMD extensions have three major omissions: no vector length register, no strided or gather/scatter data transfer instructions, and no mask registers.

- 1. Multimedia SIMD extensions fix the number of data operands in the opcode, which has led to the addition of hundreds of instructions in the MMX, SSE, and AVX extensions of the x86 architecture. Vector architectures have a vector-length register that specifies the number of operands for the current operation. These variable-length vector registers easily accommodate programs that naturally have shorter vectors than the maximum size the architecture supports. Moreover, vector architectures have an implicit maximum vector length in the

Instruction category	Operands
Unsigned add/subtract	Thirty-two 8-bit, sixteen 16-bit, eight 32-bit, or four 64-bit
Maximum/minimum	Thirty-two 8-bit, sixteen 16-bit, eight 32-bit, or four 64-bit
Average	Thirty-two 8-bit, sixteen 16-bit, eight 32-bit, or four 64-bit
Shift right/left	Thirty-two 8-bit, sixteen 16-bit, eight 32-bit, or four 64-bit
Floating point	Sixteen 16-bit, eight 32-bit, four 64-bit, or two 128-bit

Figure 4.8 Summary of typical SIMD multimedia support for 256-bit-wide operations. Note that the IEEE 754-2008 floating-point standard added half-precision (16-bit) and quad-precision (128-bit) floating-point operations.

architecture, which combined with the vector length register avoids the use of many opcodes.

2. Up until recently, multimedia SIMD did not offer the more sophisticated addressing modes of vector architectures, namely strided accesses and gather-scatter accesses. These features increase the number of programs that a vector compiler can successfully vectorize (see [Section 4.7](#)).
3. Although this is changing, multimedia SIMD usually did not offer the mask registers to support conditional execution of elements as in vector architectures.

Such omissions make it harder for the compiler to generate SIMD code and increase the difficulty of programming in SIMD assembly language.

For the x86 architecture, the MMX instructions added in 1996 repurposed the 64-bit floating-point registers, so the basic instructions could perform eight 8-bit operations or four 16-bit operations simultaneously. These were joined by parallel MAX and MIN operations, a wide variety of masking and conditional instructions, operations typically found in digital signal processors, and ad hoc instructions that were believed to be useful in important media libraries. Note that MMX reused the floating-point data-transfer instructions to access memory.

The Streaming SIMD Extensions (SSE) successor in 1999 added 16 separate registers (XMM registers) that were 128 bits wide, so now instructions could simultaneously perform sixteen 8-bit operations, eight 16-bit operations, or four 32-bit operations. It also performed parallel single-precision floating-point arithmetic. Because SSE had separate registers, it needed separate data transfer instructions. Intel soon added double-precision SIMD floating-point data types via SSE2 in 2001, SSE3 in 2004, and SSE4 in 2007. Instructions with four single-precision floating-point operations or two parallel double-precision operations increased the peak floating-point performance of the x86 computers, as long as programmers placed the operands side by side. With each generation, they also added ad hoc instructions whose aim was to accelerate specific multimedia functions perceived to be important.

The Advanced Vector Extensions (AVX), added in 2010, doubled the width of the registers again to 256 bits (YMM registers) and thereby offered instructions that double the number of operations on all narrower data types. [Figure 4.9](#) shows AVX instructions useful for double-precision floating-point computations. AVX2 in 2013 added 30 new instructions such as gather (VGATHER) and vector shifts (VPSLL, VPSRL, VPSRA). AVX-512 in 2017 doubled the width again to 512 bits (ZMM registers), doubled the number of the registers again to 32, and added about 250 new instructions including scatter (VPSCATTER) and mask registers (OPMASK). AVX includes preparations to extend registers to 1024 bits in future editions of the architecture.

In general, the goal of these extensions has been to accelerate carefully written libraries rather than for the compiler to generate them (see Appendix H), but recent x86 compilers are trying to generate such code, particularly for floating-point-intensive applications. Since the opcode determines the width of the SIMD register, every time the width doubles, so must the number of SIMD instructions.

AVX instruction	Description
VADDPD	Add four packed double-precision operands
VSUBPD	Subtract four packed double-precision operands
VMULPD	Multiply four packed double-precision operands
VDIVPD	Divide four packed double-precision operands
VFMADDPD	Multiply and add four packed double-precision operands
VFMSUBPD	Multiply and subtract four packed double-precision operands
VCMPxx	Compare four packed double-precision operands for EQ, NEQ, LT, LE, GT, GE, ...
VMOVPD	Move aligned four packed double-precision operands
VBROADCASTSD	Broadcast one double-precision operand to four locations in a 256-bit register

Figure 4.9 AVX instructions for x86 architecture useful in double-precision floating-point programs. Packed-double for 256-bit AVX means four 64-bit operands executed in SIMD mode. As the width increases with AVX, it is increasingly important to add data permutation instructions that allow combinations of narrow operands from different parts of the wide registers. AVX includes instructions that shuffle 32-bit, 64-bit, or 128-bit operands within a 256-bit register. For example, BROADCAST replicates a 64-bit operand four times in an AVX register. AVX also includes a large variety of fused multiply-add/subtract instructions; we show just two here.

Given these weaknesses, why are multimedia SIMD extensions so popular? First, they initially cost little to add to the standard arithmetic unit and they were easy to implement. Second, they require scant extra processor state compared to vector architectures, which is always a concern for context switch times. Third, you need a lot of memory bandwidth to support a vector architecture, which many computers don’t have. Fourth, SIMD does not have to deal with problems in virtual memory when a single instruction can generate 32 memory accesses and any of which can cause a page fault. The original SIMD extensions used separate data transfers per SIMD group of operands that are aligned in memory, and so they cannot cross page boundaries. Another advantage of short, fixed-length “vectors” of SIMD is that it is easy to introduce instructions that can help with new media standards, such as instructions that perform permutations or instructions that consume either fewer or more operands than vectors can produce. Finally, there was concern about how well vector architectures can work with caches. More recent vector architectures have addressed all of these problems. The overarching issue, however, is that due the overriding importance of backwards binary compatability, once an architecture gets started on the SIMD path it’s very hard to get off it.

Example To get an idea about what multimedia instructions look like, assume we added a 256-bit SIMD multimedia instruction extension to RISC-V, tentatively called RVP for “packed.” We concentrate on floating-point in this example. We add the suffix “4D” on instructions that operate on four double-precision operands at once. Like vector architectures, you can think of a SIMD Processor as having lanes, four in this case. RV64P expands the F registers to be the full width, in this case 256 bits. This example shows the RISC-V SIMD code for the DAXPY loop,

with the changes to the RISC-V code for SIMD underlined. We assume that the starting addresses of X and Y are in $x5$ and $x6$, respectively.

Answer Here is the RISC-V SIMD code:

```

      fld      f0,a           #Load scalar a
      splat.4D f0,f0        #Make 4 copies of a
      addi     x28,x5,#256    #Last address to load
Loop: fld.4D   f1,0(x5)      #Load X[i] ... X[i+3]
      fmul.4D  f1,f1,f0      #a×X[i] ... a×X[i+3]
      fld.4D   f2,0(x6)      #Load Y[i] ... Y[i+3]
      fadd.4D  f2,f2,f1      # a×X[i]+Y[i]...
                               # a×X[i+3]+Y[i+3]
      fsw.4D   f2,0(x6)      #Store Y[i]... Y[i+3]
      addi     x5,x5,#32      #Increment index to X
      addi     x6,x6,#32      #Increment index to Y
      bne      x28,x5,Loop    #Check if done

```

The changes were replacing every RISC-V double-precision instruction with its 4D equivalent, increasing the increment from 8 to 32, and adding the `splat` instruction that makes 4 copies of a in the 256 bits of $f0$. While not as dramatic as the $32\times$ reduction of dynamic instruction bandwidth of RV64V, RISC-V SIMD does get almost a $4\times$ reduction: 67 versus 258 instructions executed for RV64G. This code knows the number of elements. That number is often determined at run time, which would require an extra strip-mine loop to handle the case when the number is not a modulo of 4.

Programming Multimedia SIMD Architectures

Given the ad hoc nature of the SIMD multimedia extensions, the easiest way to use these instructions has been through libraries or by writing in assembly language.

Recent extensions have become more regular, giving compilers a more reasonable target. By borrowing techniques from vectorizing compilers, compilers are starting to produce SIMD instructions automatically. For example, advanced compilers today can generate SIMD floating-point instructions to deliver much higher performance for scientific codes. However, programmers must be sure to align all the data in memory to the width of the SIMD unit on which the code is run to prevent the compiler from generating scalar instructions for otherwise vectorizable code.

The Roofline Visual Performance Model

One visual, intuitive way to compare potential floating-point performance of variations of SIMD architectures is the Roofline model (Williams et al., 2009). The horizontal and diagonal lines of the graphs it produces give this simple model its name and indicate its value (see Figure 4.11). It ties together floating-point performance, memory performance, and arithmetic intensity in a two-dimensional graph.

Figure 4.10 Arithmetic intensity, specified as the number of floating-point operations to run the program divided by the number of bytes accessed in main memory (Williams et al., 2009). Some kernels have an arithmetic intensity that scales with problem size, such as a dense matrix, but there are many kernels with arithmetic intensities independent of problem size.

Arithmetic intensity is the ratio of floating-point operations per byte of memory accessed. It can be calculated by taking the total number of floating-point operations for a program divided by the total number of data bytes transferred to main memory during program execution. Figure 4.10 shows the relative arithmetic intensity of several example kernels.

Peak floating-point performance can be found using the hardware specifications. Many of the kernels in this case study do not fit in on-chip caches, so peak memory performance is defined by the memory system behind the caches. Note that we need the peak memory bandwidth that is available to the processors, not just at the DRAM pins as in Figure 4.27 on page 328. One way to find the (delivered) peak memory performance is to run the Stream benchmark.

Figure 4.11 shows the Roofline model for the NEC SX-9 vector processor on the left and the Intel Core i7 920 multicore computer on the right. The vertical Y -axis is achievable floating-point performance from 2 to 256 GFLOPS/s. The horizontal X -axis is arithmetic intensity, varying from 1/8 FLOP/DRAM byte accessed to 16 FLOP/DRAM byte accessed in both graphs. Note that the graph is a log-log scale, and that Rooflines are done just once for a computer.

For a given kernel, we can find a point on the X -axis based on its arithmetic intensity. If we drew a vertical line through that point, the performance of the kernel on that computer must lie somewhere along that line. We can plot a horizontal line showing peak floating-point performance of the computer. Obviously, the actual floating-point performance can be no higher than the horizontal line because that is a hardware limit.

How could we plot the peak memory performance? Because the X -axis is FLOP/byte and the Y -axis is FLOP/s, bytes/s is just a diagonal line at a 45-degree angle in this figure. Thus we can plot a third line that gives the maximum floating-point performance that the memory system of that computer can support for a given

Figure 4.11 Roofline model for one NEC SX-9 vector processor on the left and the Intel Core i7 920 multicore computer with SIMD extensions on the right (Williams et al., 2009). This Roofline is for unit-stride memory accesses and double-precision floating-point performance. NEC SX-9 is a vector supercomputer announced in 2008 that cost millions of dollars. It has a peak DP FP performance of 102.4 GFLOP/s and a peak memory bandwidth of 162 GB/s from the Stream benchmark. The Core i7 920 has a peak DP FP performance of 42.66 GFLOP/s and a peak memory bandwidth of 16.4 GB/s. The dashed vertical lines at an arithmetic intensity of 4 FLOP/byte show that both processors operate at peak performance. In this case, the SX-9 at 102.4 FLOP/s is $2.4 \times$ faster than the Core i7 at 42.66 GFLOP/s. At an arithmetic intensity of 0.25 FLOP/byte, the SX-9 is $10 \times$ faster at 40.5 GFLOP/s versus 4.1 GFLOP/s for the Core i7.

arithmetic intensity. We can express the limits as a formula to plot these lines in the graphs in Figure 4.11:

$$\text{Attainable GFLOPs/s} = \text{Min}(\text{Peak Memory BW}$$

$$\times \text{Arithmetic Intensity, Peak Floating - Point Perf.})$$

The “Roofline” sets an upper bound on performance of a kernel depending on its arithmetic intensity. If we think of arithmetic intensity as a pole that hits the roof, either it hits the flat part of the roof, which means performance is computationally limited, or it hits the slanted part of the roof, which means performance is ultimately limited by memory bandwidth. In Figure 4.11, the vertical dashed line on the right (arithmetic intensity of 4) is an example of the former and the vertical dashed line on the left (arithmetic intensity of 1/4) is an example of the latter. Given a Roofline model of a computer, you can apply it repeatedly, because it doesn’t vary by kernel.

Note that the “ridge point,” where the diagonal and horizontal roofs meet, offers an interesting insight into a computer. If it is far to the right, then only kernels with very high arithmetic intensity can achieve the maximum performance of that computer. If it is far to the left, then almost any kernel can potentially hit the maximum performance. As we will see, this vector processor has both much higher

memory bandwidth and a ridge point far to the left as compared to other SIMD Processors.

Figure 4.11 shows that the peak computational performance of the SX-9 is $2.4 \times$ faster than Core i7, but the memory performance is $10 \times$ faster. For programs with an arithmetic intensity of 0.25, the SX-9 is $10 \times$ faster (40.5 versus 4.1 GFLOP/s). The higher memory bandwidth moves the ridge point from 2.6 in the Core i7 to 0.6 on the SX-9, which means many more programs can reach the peak computational performance on the vector processor.

4.4

Graphics Processing Units

People can buy a GPU chip with thousands of parallel floating-point units for a few hundred dollars and plug it into their desk side PC. Such affordability and convenience makes high performance computing available to many. The interest in GPU computing blossomed when this potential was combined with a programming language that made GPUs easier to program. Therefore many programmers of scientific and multimedia applications today are pondering whether to use GPUs or CPUs. For programmers interested in machine learning, which is the subject of Chapter 7, GPUs are currently the preferred platform.

GPUs and CPUs do not go back in computer architecture genealogy to a common ancestor; there is no “missing link” that explains both. As Section 4.10 describes, the primary ancestors of GPUs are graphics accelerators, as doing graphics well is the reason why GPUs exist. While GPUs are moving toward mainstream computing, they can’t abandon their responsibility to continue to excel at graphics. Thus the design of GPUs may make more sense when architects ask, given the hardware invested to do graphics well, how can we supplement it to improve the performance of a wider range of applications?

Note that this section concentrates on using GPUs for computing. To see how GPU computing combines with the traditional role of graphics acceleration, see “Graphics and Computing GPUs,” by John Nickolls and David Kirk (Appendix A in the 5th edition of *Computer Organization and Design* by the same authors as this book).

Because the terminology and some hardware features are quite different from vector and SIMD architectures, we believe it will be easier if we start with the simplified programming model for GPUs before we describe the architecture.

Programming the GPU

CUDA is an elegant solution to the problem of representing parallelism in algorithms, not all algorithms, but enough to matter. It seems to resonate in some way with the way we think and code, allowing an easier, more natural expression of parallelism beyond the task level.

Vincent Natol,

“Kudos for CUDA,” *HPC Wire* (2010)

The challenge for the GPU programmer is not simply getting good performance on the GPU, but also in coordinating the scheduling of computation on the system processor and the GPU and the transfer of data between system memory and GPU memory. Moreover, as we see will see later in this section, GPUs have virtually every type of parallelism that can be captured by the programming environment: multithreading, MIMD, SIMD, and even instruction-level.

NVIDIA decided to develop a C-like language and programming environment that would improve the productivity of GPU programmers by attacking both the challenges of heterogeneous computing and of multifaceted parallelism. The name of their system is *CUDA*, for Compute Unified Device Architecture. CUDA produces C/C++ for the system processor (*host*) and a C and C++ dialect for the GPU (*device*, thus the D in CUDA). A similar programming language is *OpenCL*, which several companies are developing to offer a vendor-independent language for multiple platforms.

NVIDIA decided that the unifying theme of all these forms of parallelism is the *CUDA Thread*. Using this lowest level of parallelism as the programming primitive, the compiler and the hardware can gang thousands of CUDA Threads together to utilize the various styles of parallelism within a GPU: multithreading, MIMD, SIMD, and instruction-level parallelism. Therefore NVIDIA classifies the CUDA programming model as single instruction, multiple thread (*SIMT*). For reasons we will soon see, these threads are blocked together and executed in groups of threads, called a *Thread Block*. We call the hardware that executes a whole block of threads a *multithreaded SIMD Processor*.

We need just a few details before we can give an example of a CUDA program:

- To distinguish between functions for the GPU (device) and functions for the system processor (host), CUDA uses `__device__` or `__global__` for the former and `__host__` for the latter.
- CUDA variables declared with `__device__` are allocated to the GPU Memory (see below), which is accessible by all multithreaded SIMD Processors.
- The extended function call syntax for the function *name* that runs on the GPU is

name <<<dimGrid,dimBlock>>> (... *parameter list*...)

where *dimGrid* and *dimBlock* specify the dimensions of the code (in Thread Blocks) and the dimensions of a block (in threads).

- In addition to the identifier for blocks (*blockIdx*) and the identifier for each thread in a block (*threadIdx*), CUDA provides a keyword for the number of threads per block (*blockDim*), which comes from the *dimBlock* parameter in the preceding bullet.

Before seeing the CUDA code, let's start with conventional C code for the DAXPY loop from [Section 4.2](#):

```
// Invoke DAXPY
daxpy(n, 2.0, x, y);
// DAXPY in C
void daxpy(int n, double a, double *x, double *y)
{
    for (int i = 0; i < n; ++i)
        y[i] = a*x[i] + y[i];
}
```

Following is the CUDA version. We launch n threads, one per vector element, with 256 CUDA Threads per Thread Block in a multithreaded SIMD Processor. The GPU function starts by calculating the corresponding element index i based on the block ID, the number of threads per block, and the thread ID. As long as this index is within the array ($i < n$), it performs the multiply and add.

```
// Invoke DAXPY with 256 threads per Thread Block
__host__
int nblocks = (n + 255) / 256;
    daxpy<<<nblocks, 256>>>(n, 2.0, x, y);
// DAXPY in CUDA
__global__
void daxpy(int n, double a, double *x, double *y)
{
    int i = blockIdx.x * blockDim.x + threadIdx.x;
    if (i < n) y[i] = a*x[i] + y[i];
}
```

Comparing the C and CUDA codes, we see a common pattern to parallelizing data-parallel CUDA code. The C version has a loop where each iteration is independent from the others, allowing the loop to be transformed straightforwardly into a parallel code where each loop iteration becomes a separate thread. (As previously mentioned and described in detail in [Section 4.5](#), vectorizing compilers also rely on a lack of dependences between iterations of a loop, which are called *loop-carried dependences*.) The programmer determines the parallelism in CUDA explicitly by specifying the grid dimensions and the number of threads per SIMD Processor. By assigning a single thread to each element, there is no need to synchronize between threads when writing results to memory.

The GPU hardware handles parallel execution and thread management; it is not done by applications or by the operating system. To simplify scheduling by the hardware, CUDA requires that Thread Blocks be able to execute independently and in any order. Different Thread Blocks cannot communicate directly, although they can *coordinate* using atomic memory operations in global memory.

As we will soon see, many GPU hardware concepts are not obvious in CUDA. Writing efficient GPU code requires that programmers think in terms of SIMD

operations, even though the CUDA programming model looks like MIMD. Performance programmers must keep the GPU hardware in mind when writing in CUDA. That could hurt programmer productivity, but then most programmers are using GPUs instead of CPUs to get performance. For reasons explained shortly, they know that they need to keep groups of 32 threads together in control flow to get the best performance from multithreaded SIMD Processors and to create many more threads per multithreaded SIMD Processor to hide latency to DRAM. They also need to keep the data addresses localized in one or a few blocks of memory to get the expected memory performance.

Like many parallel systems, a compromise between productivity and performance is for CUDA to include intrinsics to give programmers explicit control over the hardware. The struggle between productivity on the one hand versus allowing the programmer to be able to express anything that the hardware can do on the other hand happens often in parallel computing. It will be interesting to see how the language evolves in this classic productivity-performance battle as well as to see whether CUDA becomes popular for other GPUs or even other architectural styles.

NVIDIA GPU Computational Structures

The uncommon heritage mentioned above helps explain why GPUs have their own architectural style and their own terminology independent from CPUs. One obstacle to understanding GPUs has been the jargon, with some terms even having misleading names. This obstacle has been surprisingly difficult to overcome, as the many rewrites of this chapter can attest.

To try to bridge the twin goals of making the architecture of GPUs understandable *and* learning the many GPU terms with nontraditional definitions, our approach is to use the CUDA terminology for software but initially use more descriptive terms for the hardware, sometimes borrowing terms from OpenCL. Once we explain the GPU architecture in our terms, we'll map them into the official jargon of NVIDIA GPUs.

From left to right, [Figure 4.12](#) lists the descriptive term used in this section, the closest term from mainstream computing, the official NVIDIA GPU jargon in case you are interested, and then a short explanation of the term. The rest of this section explains the microarchitectural features of GPUs using the descriptive terms on the left in the figure.

We use NVIDIA systems as our example as they are representative of GPU architectures. Specifically, we follow the terminology of the preceding CUDA parallel programming language and use the NVIDIA Pascal GPU as the example (see [Section 4.7](#)).

Like vector architectures, GPUs work well only with data-level parallel problems. Both styles have gather-scatter data transfers and mask registers, and GPU processors have even more registers than do vector processors. Sometimes, GPUs implement certain features in hardware that vector processors would implement in software. This difference is because vector processors have a scalar processor that can execute a software function. Unlike most vector architectures,

Type	Descriptive name	Closest old term outside of GPUs	Official CUDA/NVIDIA GPU term	Short explanation
Program abstractions	Vectorizable Loop	Vectorizable Loop	Grid	A vectorizable loop, executed on the GPU, made up of one or more Thread Blocks (bodies of vectorized loop) that can execute in parallel
	Body of Vectorized Loop	Body of a (Strip-Mined) Vectorized Loop	Thread Block	A vectorized loop executed on a multithreaded SIMD Processor, made up of one or more threads of SIMD instructions. They can communicate via local memory
	Sequence of SIMD Lane Operations	One iteration of a Scalar Loop	CUDA Thread	A vertical cut of a thread of SIMD instructions corresponding to one element executed by one SIMD Lane. Result is stored depending on mask and predicate register
Machine object	A Thread of SIMD Instructions	Thread of Vector Instructions	Warp	A traditional thread, but it only contains SIMD instructions that are executed on a multithreaded SIMD Processor. Results stored depending on a per-element mask
	SIMD Instruction	Vector Instruction	PTX Instruction	A single SIMD instruction executed across SIMD Lanes
Processing hardware	Multithreaded SIMD Processor	(Multithreaded) Vector Processor	Streaming Multiprocessor	A multithreaded SIMD Processor executes threads of SIMD instructions, independent of other SIMD Processors
	Thread Block Scheduler	Scalar Processor	Giga Thread Engine	Assigns multiple Thread Blocks (bodies of vectorized loop) to multithreaded SIMD Processors
	SIMD Thread Scheduler	Thread Scheduler in a Multithreaded CPU	Warp Scheduler	Hardware unit that schedules and issues threads of SIMD instructions when they are ready to execute; includes a scoreboard to track SIMD Thread execution
	SIMD Lane	Vector Lane	Thread Processor	A SIMD Lane executes the operations in a thread of SIMD instructions on a single element. Results stored depending on mask
Memory hardware	GPU Memory	Main Memory	Global Memory	DRAM memory accessible by all multithreaded SIMD Processors in a GPU
	Private Memory	Stack or Thread Local Storage (OS)	Local Memory	Portion of DRAM memory private to each SIMD Lane
	Local Memory	Local Memory	Shared Memory	Fast local SRAM for one multithreaded SIMD Processor, unavailable to other SIMD Processors
	SIMD Lane Registers	Vector Lane Registers	Thread Processor Registers	Registers in a single SIMD Lane allocated across a full Thread Block (body of vectorized loop)

Figure 4.12 Quick guide to GPU terms used in this chapter. We use the first column for hardware terms. Four groups cluster these 11 terms. From top to bottom: program abstractions, machine objects, processing hardware, and memory hardware. [Figure 4.21](#) on page 312 associates vector terms with the closest terms here, and [Figure 4.24](#) on page 317 and [Figure 4.25](#) on page 318 reveal the official CUDA/NVIDIA and AMD terms and definitions along with the terms used by OpenCL.

GPUs also rely on multithreading within a single multithreaded SIMD Processor to hide memory latency (see Chapters 2 and 3). However, efficient code for both vector architectures and GPUs requires programmers to think in groups of SIMD operations.

A *Grid* is the code that runs on a GPU that consists of a set of *Thread Blocks*. Figure 4.12 draws the analogy between a grid and a vectorized loop and between a Thread Block and the body of that loop (after it has been strip-mined, so that it is a full computation loop). To give a concrete example, let's suppose we want to multiply two vectors together, each 8192 elements long: $A = B * C$. We'll return to this example throughout this section. Figure 4.13 shows the relationship between this example and these first two GPU terms. The GPU code that works on the whole 8192 element multiply is called a *Grid* (or vectorized loop). To break it down into more manageable sizes, a Grid is composed of *Thread Blocks* (or body of a vectorized loop), each with up to 512 elements. Note that a SIMD instruction executes 32 elements at a time. With 8192 elements in the vectors, this example thus has 16 Thread Blocks because $16 = 8192 \div 512$. The Grid and Thread Block are programming abstractions implemented in GPU hardware that help programmers organize their CUDA code. (The Thread Block is analogous to a strip-mined vector loop with a vector length of 32.)

A Thread Block is assigned to a processor that executes that code, which we call a *multithreaded SIMD Processor*, by the *Thread Block Scheduler*. The programmer tells the Thread Block Scheduler, which is implemented in hardware, how many Thread Blocks to run. In this example, it would send 16 Thread Blocks to multithreaded SIMD Processors to compute all 8192 elements of this loop

Figure 4.14 shows a simplified block diagram of a multithreaded SIMD Processor. It is similar to a vector processor, but it has many parallel functional units instead of a few that are deeply pipelined, as in a vector processor. In the programming example in Figure 4.13, each multithreaded SIMD Processor is assigned 512 elements of the vectors to work on. SIMD Processors are full processors with separate PCs and are programmed using threads (see Chapter 3).

The GPU hardware then contains a collection of multithreaded SIMD Processors that execute a Grid of Thread Blocks (bodies of vectorized loop); that is, a GPU is a multiprocessor composed of multithreaded SIMD Processors.

A GPU can have from one to several dozen multithreaded SIMD Processors. For example, the Pascal P100 system has 56, while the smaller chips may have as few as one or two. To provide transparent scalability across models of GPUs with a differing number of multithreaded SIMD Processors, the Thread Block Scheduler assigns Thread Blocks (bodies of a vectorized loop) to multithreaded SIMD Processors. Figure 4.15 shows the floor plan of the P100 implementation of the Pascal architecture.

Dropping down one more level of detail, the machine object that the hardware creates, manages, schedules, and executes is a *thread of SIMD instructions*. It is a traditional thread that contains exclusively SIMD instructions. These threads of SIMD instructions have their own PCs, and they run on a multithreaded SIMD Processor. The *SIMD Thread Scheduler* knows which threads of SIMD instructions are ready to run and then sends them off to a dispatch unit to be run on

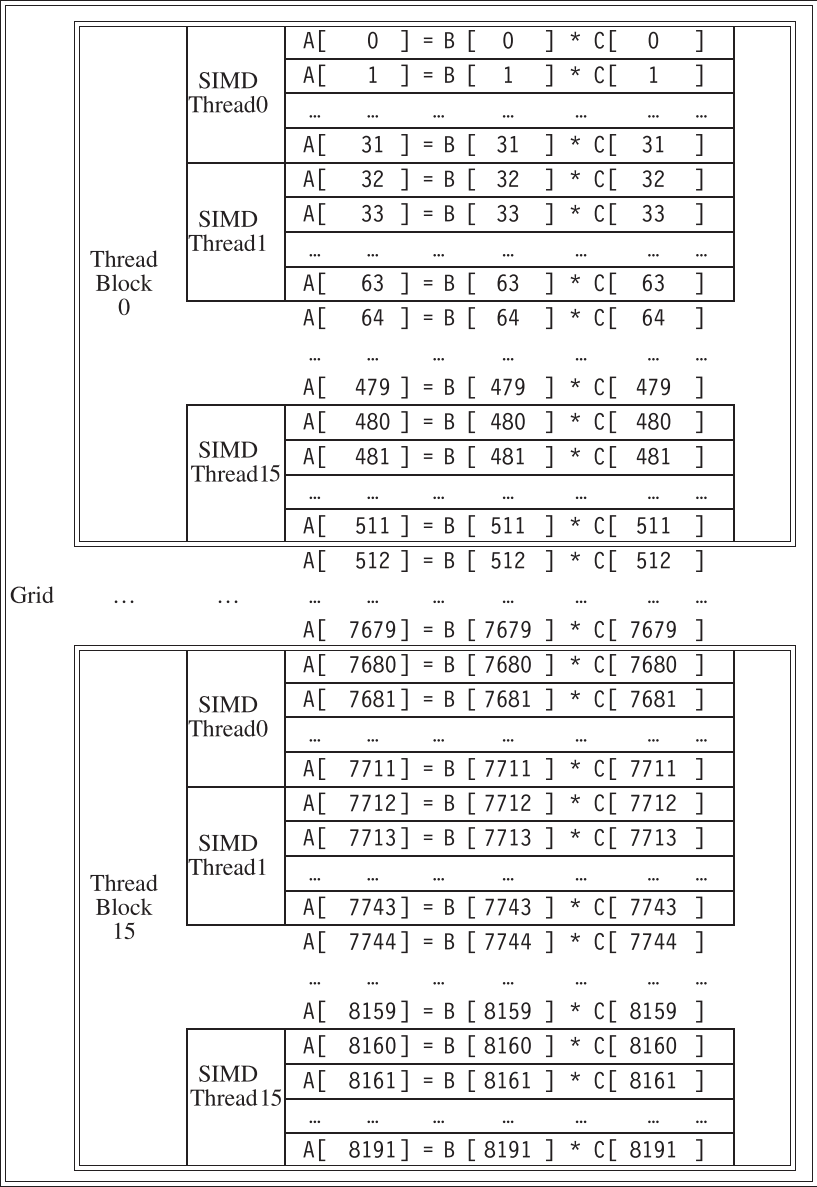

Figure 4.13 The mapping of a Grid (vectorizable loop), Thread Blocks (SIMD basic blocks), and threads of SIMD instructions to a vector-vector multiply, with each vector being 8192 elements long. Each thread of SIMD instructions calculates 32 elements per instruction, and in this example, each Thread Block contains 16 threads of SIMD instructions and the Grid contains 16 Thread Blocks. The hardware Thread Block Scheduler assigns Thread Blocks to multithreaded SIMD Processors, and the hardware Thread Scheduler picks which thread of SIMD instructions to run each clock cycle within a SIMD Processor. Only SIMD Threads in the same Thread Block can communicate via local memory. (The maximum number of SIMD Threads that can execute simultaneously per Thread Block is 32 for Pascal GPUs.)

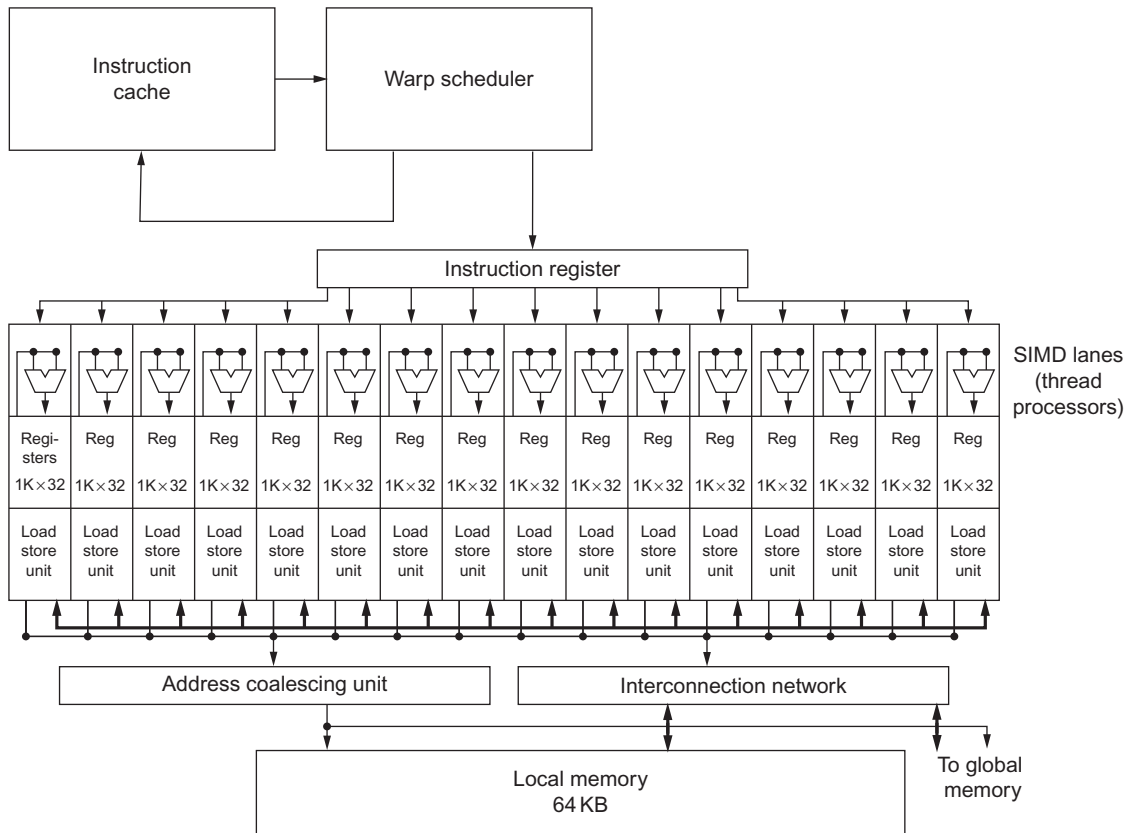

Figure 4.14 Simplified block diagram of a multithreaded SIMD Processor. It has 16 SIMD Lanes. The SIMD Thread Scheduler has, say, 64 independent threads of SIMD instructions that it schedules with a table of 64 program counters (PCs). Note that each lane has 1024 32-bit registers.

the multithreaded SIMD Processor. Thus GPU hardware has two levels of hardware schedulers: (1) the *Thread Block Scheduler* that assigns Thread Blocks (bodies of vectorized loops) to multithreaded SIMD Processors and (2) the SIMD Thread Scheduler *within* a SIMD Processor, which schedules when threads of SIMD instructions should run.

The SIMD instructions of these threads are 32 wide, so each thread of SIMD instructions in this example would compute 32 of the elements of the computation. In this example, Thread Blocks would contain $512/32 = 16$ SIMD Threads (see Figure 4.13).

Because the thread consists of SIMD instructions, the SIMD Processor must have parallel functional units to perform the operation. We call them *SIMD Lanes*, and they are quite similar to the Vector Lanes in Section 4.2.

Figure 4.15 Full-chip block diagram of the Pascal P100 GPU. It has 56 multithreaded SIMD Processors, each with an L1 cache and local memory, 32 L2 units, and a memory-bus width of 4096 data wires. (It has 60 blocks, with four spares to improve yield.) The P100 has 4 HBM2 ports supporting up to 16 GB of capacity. It contains 15.4 billion transistors.

With the Pascal GPU, each 32-wide thread of SIMD instructions is mapped to 16 physical SIMD Lanes, so each SIMD instruction in a thread of SIMD instructions takes 2 clock cycles to complete. Each thread of SIMD instructions is executed in lock step and scheduled only at the beginning. Staying with the analogy of a SIMD Processor as a vector processor, you could say that it has 16 lanes, the vector length is 32, and the chime is 2 clock cycles. (This wide but shallow nature is why we use the more accurate term SIMD Processor rather than vector.)

Note that the number of lanes in a GPU SIMD Processor can be anything up to the number of threads in a Thread Block, just as the number of lanes in a vector processor can vary between 1 and the maximum vector length. For example, across GPU generations, the number of lanes per SIMD Processor has fluctuated between 8 and 32.

Because by definition the threads of SIMD instructions are independent, the SIMD Thread Scheduler can pick whatever thread of SIMD instructions is ready, and need not stick with the next SIMD instruction in the sequence within a thread. The SIMD Thread Scheduler includes a scoreboard (see [Chapter 3](#)) to keep track of up to 64 threads of SIMD instructions to see which SIMD instruction is ready to go. The latency of memory instructions is variable because of hits and misses in the caches and the TLB, thus the requirement of a scoreboard to determine when these instructions are complete. [Figure 4.16](#) shows the SIMD Thread Scheduler picking threads of SIMD instructions in a different order over time. The assumption of GPU architects is that GPU applications have so many threads of SIMD instructions that multithreading can both hide the latency to DRAM and increase utilization of multithreaded SIMD Processors.

Figure 4.16 Scheduling of threads of SIMD instructions. The scheduler selects a ready thread of SIMD instructions and issues an instruction synchronously to all the SIMD Lanes executing the SIMD Thread. Because threads of SIMD instructions are independent, the scheduler may select a different SIMD Thread each time.

Continuing our vector multiply example, each multithreaded SIMD Processor must load 32 elements of two vectors from memory into registers, perform the multiply by reading and writing registers, and store the product back from registers into memory. To hold these memory elements, a SIMD Processor has between an impressive 32,768–65,536 32-bit registers (1024 per lane in [Figure 4.14](#)), depending on the model of the Pascal GPU. Just like a vector processor, these registers are divided logically across the Vector Lanes or, in this case, SIMD Lanes.

Each SIMD Thread is limited to no more than 256 registers, so you might think of a SIMD Thread as having up to 256 vector registers, with each vector register having 32 elements and each element being 32 bits wide. (Because double-precision floating-point operands use two adjacent 32-bit registers, an alternative view is that each SIMD Thread has 128 vector registers of 32 elements, each of which is 64 bits wide.)

There is a trade-off between register use and maximum number of threads; fewer registers per thread means more threads are possible, and more registers

mean fewer threads. That is, not all SIMD Threads need to have the maximum number of registers. Pascal architects believe much of this precious silicon area would be idle if all threads had the maximum number of registers.

To be able to execute many threads of SIMD instructions, each is dynamically allocated a set of the physical registers on each SIMD Processor when threads of SIMD instructions are created and freed when the SIMD Thread exits. For example, a programmer can have a Thread Block that uses 36 registers per thread with, say, 16 SIMD Threads alongside another Thread Block that has 20 registers per thread with 32 SIMD Threads. Subsequent Thread Blocks may show up in any order, and the registers have to be allocated on demand. While this variability can lead to fragmentation and make some registers unavailable, in practice most Thread Blocks use the same number of registers for a given vectorizable loop (“grid”). The hardware must know where the registers for each Thread Block are in the large register file, and this is recorded on a per Thread-Block basis. This flexibility requires routing, arbitration, and banking in the hardware because a specific register for a given Thread Block could end up in any location in the register file.

Note that a CUDA Thread is just a vertical cut of a thread of SIMD instructions, corresponding to one element executed by one SIMD Lane. Beware that CUDA Threads are very different from POSIX Threads; you can’t make arbitrary system calls from a CUDA Thread.

We’re now ready to see what GPU instructions look like.

NVIDIA GPU Instruction Set Architecture

Unlike most system processors, the instruction set target of the NVIDIA compilers is an abstraction of the hardware instruction set. *PTX* (*Parallel Thread Execution*) provides a stable instruction set for compilers as well as compatibility across generations of GPUs. The hardware instruction set is hidden from the programmer. PTX instructions describe the operations on a single CUDA Thread and usually map one-to-one with hardware instructions, but one PTX instruction can expand to many machine instructions, and vice versa. PTX uses an unlimited number of write-once registers and the compiler must run a register allocation procedure to map the PTX registers to a fixed number of read-write hardware registers available on the actual device. The optimizer runs subsequently and can reduce register use even further. This optimizer also eliminates dead code, folds instructions together, and calculates places where branches might diverge and places where diverged paths could converge.

Although there is some similarity between the x86 microarchitecture and PTX, in that both translate to an internal form (microinstructions for x86), the difference is that this translation happens in hardware at runtime during execution on the x86 versus in software and load time on a GPU.

The format of a PTX instruction is

```
opcode.type d, a, b, c;
```

where *d* is the destination operand; *a*, *b*, and *c* are source operands; and the operation type is one of the following:

Type	.type specifier
Untyped bits 8, 16, 32, and 64 bits	.b8, .b16, .b32, .b64
Unsigned integer 8, 16, 32, and 64 bits	.u8, .u16, .u32, .u64
Signed integer 8, 16, 32, and 64 bits	.s8, .s16, .s32, .s64
Floating Point 16, 32, and 64 bits	.f16, .f32, .f64

Source operands are 32-bit or 64-bit registers or a constant value. Destinations are registers, except for store instructions.

Figure 4.17 shows the basic PTX instruction set. All instructions can be predicated by 1-bit predicate registers, which can be set by a set predicate instruction (`setp`). The control flow instructions are functions `call` and `return`, thread `exit`, `branch`, and barrier synchronization for threads within a Thread Block (`bar.sync`). Placing a predicate in front of a branch instruction gives us conditional branches. The compiler or PTX programmer declares virtual registers as 32-bit or 64-bit typed or untyped values. For example, `R0`, `R1`, . . . are for 32-bit values and `RD0`, `RD1`, . . . are for 64-bit registers. Recall that the assignment of virtual registers to physical registers occurs at load time with PTX.

The following sequence of PTX instructions is for one iteration of our DAXPY loop on page 292:

```

shl.u32 R8, blockIdx, 8    ; Thread Block ID * Block size
                           ; (256 or 28)
add.u32 R8, R8, threadIdx ; R8 = i = my CUDA Thread ID
shl.u32 R8, R8, 3          ; byte offset
ld.global.f64 RD0, [X+R8]; RD0 = X[i]
ld.global.f64 RD2, [Y+R8]; RD2 = Y[i]
mul.f64 RD0, RD0, RD4      ; Product in RD0 = RD0 * RD4
                           ; (scalar a)
add.f64 RD0, RD0, RD2      ; Sum in RD0 = RD0 + RD2 (Y[i])
st.global.f64 [Y+R8], RD0; Y[i] = sum (X[i]*a + Y[i])

```

As demonstrated above, the CUDA programming model assigns one CUDA Thread to each loop iteration and offers a unique identifier number to each Thread Block (`blockIdx`) and one to each CUDA Thread within a block (`threadIdx`). Thus it creates 8192 CUDA Threads and uses the unique number to address each element within the array, so there is no incrementing or branching code. The first three PTX instructions calculate that unique element byte offset in `R8`, which is added to the base of the arrays. The following PTX instructions load two double-precision floating-point operands, multiply and add them, and store the sum. (We'll describe the PTX code corresponding to the CUDA code "`if (i < n)`" below.)

Note that unlike vector architectures, GPUs don't have separate instructions for sequential data transfers, strided data transfers, and gather-scatter data transfers.

Group	Instruction	Example	Meaning	Comments
Arithmetic	arithmetic.type = .s32, .u32, .f32, .s64, .u64, .f64			
	add.type	add.f32 d, a, b	$d = a + b;$	
	sub.type	sub.f32 d, a, b	$d = a - b;$	
	mul.type	mul.f32 d, a, b	$d = a * b;$	
	mad.type	mad.f32 d, a, b, c	$d = a * b + c;$	multiply-add
	div.type	div.f32 d, a, b	$d = a / b;$	multiple microinstructions
	rem.type	rem.u32 d, a, b	$d = a \% b;$	integer remainder
	abs.type	abs.f32 d, a	$d = a ;$

Figure 4.17 Basic PTX GPU thread instructions.

All data transfers are gather-scatter! To regain the efficiency of sequential (unit-stride) data transfers, GPUs include special Address Coalescing hardware to recognize when the SIMD Lanes within a thread of SIMD instructions are collectively issuing sequential addresses. That runtime hardware then notifies the Memory Interface Unit to request a block transfer of 32 sequential words. To get this important performance improvement, the GPU programmer must ensure that adjacent CUDA Threads access nearby addresses at the same time so that they can be coalesced into one or a few memory or cache blocks, which our example does.

Conditional Branching in GPUs

Just like the case with unit-stride data transfers, there are strong similarities between how vector architectures and GPUs handle IF statements, with the former implementing the mechanism largely in software with limited hardware support and the latter making use of even more hardware. As we will see, in addition to explicit predicate registers, GPU branch hardware uses internal masks, a branch synchronization stack, and instruction markers to manage when a branch diverges into multiple execution paths and when the paths converge.

At the PTX assembler level, control flow of one CUDA Thread is described by the PTX instructions `branch`, `call`, `return`, and `exit`, plus individual per-thread-lane predication of each instruction, specified by the programmer with per-thread-lane 1-bit predicate registers. The PTX assembler analyzes the PTX branch graph and optimizes it to the fastest GPU hardware instruction sequence. Each can make its own decision on a branch and does not need to be in lock step.

At the GPU hardware instruction level, control flow includes `branch`, `jump`, `jump indexed`, `call`, `call indexed`, `return`, `exit`, and special instructions that manage the branch synchronization stack. GPU hardware provides each SIMD Thread with its own stack; a stack entry contains an identifier token, a target instruction address, and a target thread-active mask. There are GPU special instructions that push stack entries for a SIMD Thread and special instructions and instruction markers that pop a stack entry or unwind the stack to a specified entry and branch to the target instruction address with the target thread-active mask. GPU hardware instructions also have an individual per-lane predication (enable/disable), specified with a 1-bit predicate register for each lane.

The PTX assembler typically optimizes a simple outer-level IF-THEN-ELSE statement coded with PTX branch instructions to solely predicated GPU instructions, without any GPU branch instructions. A more complex control flow often results in a mixture of predication and GPU branch instructions with special instructions and markers that use the branch synchronization stack to push a stack entry when some lanes branch to the target address, while others fall through. NVIDIA says a branch *diverges* when this happens. This mixture is also used when a SIMD Lane executes a synchronization marker or *converges*, which pops a stack entry and branches to the stack-entry address with the stack-entry thread-active mask.

The PTX assembler identifies loop branches and generates GPU branch instructions that branch to the top of the loop, along with special stack instructions to handle individual lanes breaking out of the loop and converging the SIMD Lanes when all lanes have completed the loop. GPU indexed jump and indexed call instructions push entries on the stack so that when all lanes complete the switch statement or function call, the SIMD Thread converges.

A GPU set predicate instruction (`setp` in [Figure 4.17](#)) evaluates the conditional part of the IF statement. The PTX branch instruction then depends on that predicate. If the PTX assembler generates predicated instructions with no GPU branch instructions, it uses a per-lane predicate register to enable or disable each SIMD Lane for each instruction. The SIMD instructions in the threads inside the THEN part of the IF statement broadcast operations to all the SIMD Lanes. Those lanes with the predicate set to 1 perform the operation and store the result, and the other SIMD Lanes don't perform an operation or store a result. For the ELSE statement, the instructions use the complement of the predicate (relative to the THEN statement), so the SIMD Lanes that were idle now perform the operation and store the result while their formerly active siblings don't. At the end of the ELSE statement, the instructions are unpredicated so the original computation can proceed. Thus, for equal length paths, an IF-THEN-ELSE operates at 50% efficiency or less.

IF statements can be nested, thus the use of a stack, and the PTX assembler typically generates a mix of predicated instructions and GPU branch and special synchronization instructions for complex control flow. Note that deep nesting can mean that most SIMD Lanes are idle during execution of nested conditional statements. Thus, doubly nested IF statements with equal-length paths run at 25% efficiency, triply nested at 12.5% efficiency, and so on. The analogous case would be a vector processor operating where only a few of the mask bits are ones.

Dropping down a level of detail, the PTX assembler sets a “branch synchronization” marker on appropriate conditional branch instructions that pushes the current active mask on a stack inside each SIMD Thread. If the conditional branch diverges (some lanes take the branch but some fall through), it pushes a stack entry and sets the current internal active mask based on the condition. A branch synchronization marker pops the diverged branch entry and flips the mask bits before the ELSE portion. At the end of the IF statement, the PTX assembler adds another branch synchronization marker that pops the prior active mask off the stack into the current active mask.

If all the mask bits are set to 1, then the branch instruction at the end of the THEN skips over the instructions in the ELSE part. There is a similar optimization for the THEN part in case all the mask bits are 0 because the conditional branch jumps over the THEN instructions. Parallel IF statements and PTX branches often use branch conditions that are unanimous (all lanes agree to follow the same path) such that the SIMD Thread does not diverge into a different individual lane control flow. The PTX assembler optimizes such branches to skip over blocks of instructions that are not executed by any lane of a SIMD Thread. This optimization is

useful in conditional error checking, for example, where the test must be made but is rarely taken.

The code for a conditional statement similar to the one in [Section 4.2](#) is

```
if (X[i] != 0)
    X[i] = X[i] - Y[i];
else X[i] = Z[i];
```

This IF statement could compile to the following PTX instructions (assuming that R8 already has the scaled thread ID), with **Push*, **Comp*, **Pop* indicating the branch synchronization markers inserted by the PTX assembler that push the old mask, complement the current mask, and pop to restore the old mask:

```
ld.global.f64 RD0, [X+R8]          ; RD0 = X[i]
setp.neq.s32 P1, RD0, #0           ; P1 is predicate reg 1
@!P1, bra ELSE1, *Push             ; Push old mask, set new
                                   ; mask bits if P1 false, go to ELSE1
ld.global.f64 RD2, [Y+R8]          ; RD2 = Y[i]
sub.f64 RD0, RD0, RD2              ; Difference in RD0
st.global.f64 [X+R8], RD0          ; X[i] = RD0
@P1, bra ENDIF1, *Comp             ; complement mask bits
                                   ; if P1 true, go to ENDIF1
ELSE1: ld.global.f64 RD0, [Z+R8]    ; RD0 = Z[i]
       st.global.f64 [X+R8], RD0    ; X[i] = RD0
ENDIF1:<next instruction>, *Pop     ; pop to restore old mask
```

Once again, normally all instructions in the IF-THEN-ELSE statement are executed by a SIMD Processor. It's just that only some of the SIMD Lanes are enabled for the THEN instructions and some lanes for the ELSE instructions. As previously mentioned, in the surprisingly common case that the individual lanes agree on the predicated branch—such as branching on a parameter value that is the same for all lanes so that all active mask bits are 0s or all are 1s—the branch skips the THEN instructions or the ELSE instructions.

This flexibility makes it appear that an element has its own program counter; however, in the slowest case, only one SIMD Lane could store its result every 2 clock cycles, with the rest idle. The analogous slowest case for vector architectures is operating with only one mask bit set to 1. This flexibility can lead naive GPU programmers to poor performance, but it can be helpful in the early stages of program development. Keep in mind, however, that the only choice for a SIMD Lane in a clock cycle is to perform the operation specified in the PTX instruction or be idle; two SIMD Lanes cannot simultaneously execute different instructions.

This flexibility also helps explain the name *CUDA Thread* given to each element in a thread of SIMD instructions, because it gives the illusion of acting independently. A naive programmer may think that this thread abstraction means GPUs handle conditional branches more gracefully. Some threads go one way, the rest go

another, which seems true as long as you're not in a hurry. Each CUDA Thread is either executing the same instruction as every other thread in the Thread Block or it is idle. This synchronization makes it easier to handle loops with conditional branches because the mask capability can turn off SIMD Lanes and it detects the end of the loop automatically.

The resulting performance sometimes belies that simple abstraction. Writing programs that operate SIMD Lanes in this highly independent MIMD mode is like writing programs that use lots of virtual address space on a computer with a smaller physical memory. Both are correct, but they may run so slowly that the programmer will not be pleased with the result.

Conditional execution is a case where GPUs do in runtime hardware what vector architectures do at compile time. Vector compilers do a double IF-conversion, generating four different masks. The execution is basically the same as GPUs, but there are some more overhead instructions executed for vectors. Vector architectures have the advantage of being integrated with a scalar processor, allowing them to avoid the time for the 0 cases when they dominate a calculation. Although it will depend on the speed of the scalar processor versus the vector processor, the cross-over point when it's better to use scalar might be when less than 20% of the mask bits are 1s. One optimization available at runtime for GPUs, but not at compile time for vector architectures, is to skip the THEN or ELSE parts when mask bits are all 0s or all 1s.

Thus the efficiency with which GPUs execute conditional statements comes down to how frequently the branches will diverge. For example, one calculation of eigenvalues has deep conditional nesting, but measurements of the code show that around 82% of clock cycle issues have between 29 and 32 out of the 32 mask bits set to 1, so GPUs execute this code more efficiently than one might expect.

Note that the same mechanism handles the strip-mining of vector loops—when the number of elements doesn't perfectly match the hardware. The example at the beginning of this section shows that an IF statement checks to see if this SIMD Lane element number (stored in `R8` in the preceding example) is less than the limit (`i < n`), and it sets masks appropriately.

NVIDIA GPU Memory Structures

Figure 4.18 shows the memory structures of an NVIDIA GPU. Each SIMD Lane in a multithreaded SIMD Processor is given a private section of off-chip DRAM, which we call the *private memory*. It is used for the stack frame, for spilling registers, and for private variables that don't fit in the registers. SIMD Lanes do *not* share private memories. GPUs cache this private memory in the L1 and L2 caches to aid register spilling and to speed up function calls.

We call the on-chip memory that is local to each multithreaded SIMD Processor *local memory*. It is a small scratchpad memory with low latency (a few dozen clocks) and high bandwidth (128 bytes/clock) where the programmer can store data that needs to be reused, either by the same thread or another thread in the same

Figure 4.18 GPU memory structures. GPU memory is shared by all Grids (vectorized loops), local memory is shared by all threads of SIMD instructions within a Thread Block (body of a vectorized loop), and private memory is private to a single CUDA Thread. Pascal allows preemption of a Grid, which requires that all local and private memory be able to be saved in and restored from global memory. For completeness sake, the GPU can also access CPU memory via the PCIe bus. This path is commonly used for a final result when its address is in host memory. This option eliminates a final copy from the GPU memory to the host memory.

Thread Block. Local memory is limited in size, typically to 48 KiB. It carries no state between Thread Blocks executed on the same processor. It is shared by the SIMD Lanes within a multithreaded SIMD Processor, but this memory is not shared between multithreaded SIMD Processors. The multithreaded SIMD Processor dynamically allocates portions of the local memory to a Thread Block when it creates the Thread Block, and frees the memory when all the threads of the Thread Block exit. That portion of local memory is private to that Thread Block.

Finally, we call the off-chip DRAM shared by the whole GPU and all Thread Blocks *GPU Memory*. Our vector multiply example used only GPU Memory.

The system processor, called the *host*, can read or write GPU Memory. Local memory is unavailable to the host, as it is private to each multithreaded SIMD Processor. Private memories are unavailable to the host as well.

Rather than rely on large caches to contain the whole working sets of an application, GPUs traditionally use smaller streaming caches and, because their working sets can be hundreds of megabytes, rely on extensive multithreading of threads of SIMD instructions to hide the long latency to DRAM. Given the use of multithreading to hide DRAM latency, the chip area used for large L2 and L3 caches in system processors is spent instead on computing resources and on the large number of registers to hold the state of many threads of SIMD instructions. In contrast, as mentioned, vector loads and stores amortize the latency across many elements because they pay the latency only once and then pipeline the rest of the accesses.

Although hiding memory latency behind many threads was the original philosophy of GPUs and vector processors, all recent GPUs and vector processors have caches to reduce latency. The argument follows Little's Law from queuing theory: the longer the latency, the more threads need to run during a memory access, which in turn requires more registers. Thus GPU caches are added to lower average latency and thereby mask potential shortages of the number of registers.

To improve memory bandwidth and reduce overhead, as mentioned, PTX data transfer instructions in cooperation with the memory controller coalesce individual parallel thread requests from the same SIMD Thread together into a single memory block request when the addresses fall in the same block. These restrictions are placed on the GPU program, somewhat analogous to the guidelines for system processor programs to engage hardware prefetching (see [Chapter 2](#)). The GPU memory controller will also hold requests and send ones together to the same open page to improve memory bandwidth (see [Section 4.6](#)). [Chapter 2](#) describes DRAM in sufficient detail for readers to understand the potential benefits of grouping related addresses.

Innovations in the Pascal GPU Architecture

The multithreaded SIMD Processor of Pascal is more complicated than the simplified version in [Figure 4.20](#). To increase hardware utilization, each SIMD Processor has two SIMD Thread Schedulers, each with multiple instruction dispatch units (some GPUs have four thread schedulers). The dual SIMD Thread Scheduler selects two threads of SIMD instructions and issues one instruction from each to two sets of 16 SIMD Lanes, 16 load/store units, or 8 special function units. With multiple execution units available, two threads of SIMD instructions are scheduled each clock cycle, allowing 64 lanes to be active. Because the threads are independent, there is no need to check for data dependences in the instruction stream. This innovation would be analogous to a multithreaded vector processor that can issue vector instructions from two independent threads. [Figure 4.19](#) shows the Dual Scheduler issuing instructions, and [Figure 4.20](#) shows the block diagram of the multithreaded SIMD Processor of a Pascal GP100 GPU.

Each new generation of GPU typically adds some new features that increase performance or make it easier for programmers. Here are the four main innovations of Pascal:

Figure 4.19 Block diagram of Pascal's dual SIMD Thread scheduler. Compare this design to the single SIMD Thread design in [Figure 4.16](#).

- *Fast single-precision, double-precision, and half-precision floating-point arithmetic*—Pascal GP100 chip has significant floating-point performance in three sizes, all part of the IEEE standard for floating-point. The single-precision floating-point of the GPU runs at a peak of 10 TeraFLOP/s. Double-precision is roughly half-speed at 5 TeraFLOP/s, and half-precision is about double-speed at 20 TeraFLOP/s when expressed as 2-element vectors. The atomic memory operations include floating-point add for all three sizes. Pascal GP100 is the first GPU with such high performance for half-precision.
- *High-bandwidth memory*—The next innovation of the Pascal GP100 GPU is the use of stacked, high-bandwidth memory (*HBM2*). This memory has a wide bus with 4096 data wires running at 0.7 GHz offering a peak bandwidth of 732 GB/s, which is more than twice as fast as previous GPUs.
- *High-speed chip-to-chip interconnect*—Given the coprocessor nature of GPUs, the PCI bus can be a communications bottleneck when trying to use multiple GPUs with one CPU. Pascal GP100 introduces the *NVLink* communications channel that supports data transfers of up to 20 GB/s in each direction. Each GP100 has 4 NVLink channels, providing a peak aggregate chip-to-chip bandwidth of 160 GB/s per chip. Systems with 2, 4, and 8 GPUs are available for multi-GPU applications, where each GPU can perform load, store, and atomic operations to any GPU connected by NVLink. Additionally, an NVLink channel can communicate with the CPU in some cases. For example, the IBM Power9 CPU supports CPU-GPU communication. In this chip, NVLink provides a coherent view of memory between all GPUs and CPUs connected together. It also provides cache-to-cache communication instead of memory-to-memory communication.

Figure 4.20 Block diagram of the multithreaded SIMD Processor of a Pascal GPU. Each of the 64 SIMD Lanes (cores) has a pipelined floating-point unit, a pipelined integer unit, some logic for dispatching instructions and operands to these units, and a queue for holding results. The 64 SIMD Lanes interact with 32 double-precision ALUs (DP units) that perform 64-bit floating-point arithmetic, 16 load-store units (LD/STs), and 16 special function units (SFUs) that calculate functions such as square roots, reciprocals, sines, and cosines.

- *Unified virtual memory and paging support*—The Pascal GP100 GPU adds page-fault capabilities within a unified virtual address space. This feature allows a single virtual address for every data structure that is identical across all the GPUs and CPUs in a single system. When a thread accesses an address that is remote, a page of memory is transferred to the local GPU for subsequent use. Unified memory simplifies the programming model by providing demand paging instead of explicit memory copying between the CPU and GPU or

between GPUs. It also allows allocating far more memory than exists on the GPU to solve problems with large memory requirements. As with any virtual memory system, care must be taken to avoid excessive page movement.

Similarities and Differences Between Vector Architectures and GPUs

As we have seen, there really are many similarities between vector architectures and GPUs. Along with the quirky jargon of GPUs, these similarities have contributed to the confusion in architecture circles about how novel GPUs really are. Now that you’ve seen what is under the covers of vector computers and GPUs, you can appreciate both the similarities and the differences. Because both architectures are designed to execute data-level parallel programs, but take different paths, this comparison is in depth in order to provide a better understanding of what is needed for DLP hardware. [Figure 4.21](#) shows the vector term first and then the closest equivalent in a GPU.

A SIMD Processor is like a vector processor. The multiple SIMD Processors in GPUs act as independent MIMD cores, just as many vector computers have multiple vector processors. This view will consider the NVIDIA Tesla P100 as a 56-core machine with hardware support for multithreading, where each core has 64 lanes. The biggest difference is multithreading, which is fundamental to GPUs and missing from most vector processors.

Looking at the registers in the two architectures, the RV64V register file in our implementation holds entire vectors—that is, a contiguous block of elements. In contrast, a single vector in a GPU will be distributed across the registers of all SIMD Lanes. A RV64V processor has 32 vector registers with perhaps 32 elements, or 1024 elements total. A GPU thread of SIMD instructions has up to 256 registers with 32 elements each, or 8192 elements. These extra GPU registers support multithreading.

[Figure 4.22](#) is a block diagram of the execution units of a vector processor on the left and a multithreaded SIMD Processor of a GPU on the right. For pedagogic purposes, we assume the vector processor has four lanes and the multithreaded SIMD Processor also has four SIMD Lanes. This figure shows that the four SIMD Lanes act in concert much like a four-lane vector unit, and that a SIMD Processor acts much like a vector processor.

In reality, there are many more lanes in GPUs, so GPU “chimes” are shorter. While a vector processor might have 2 to 8 lanes and a vector length of, say, 32—making a chime 4 to 16 clock cycles—a multithreaded SIMD Processor might have 8 or 16 lanes. A SIMD Thread is 32 elements wide, so a GPU chime would just be 2 or 4 clock cycles. This difference is why we use “SIMD Processor” as the more descriptive term because it is closer to a SIMD design than it is to a traditional vector processor design.

Type	Vector term	Closest CUDA/NVIDIA GPU term	Comment
Program abstractions	Vectorized Loop	Grid	Concepts are similar, with the GPU using the less descriptive term
	Chime	—	Because a vector instruction (PTX instruction) takes just 2 cycles on Pascal to complete, a chime is short in GPUs. Pascal has two execution units that support the most common floating-point instructions that are used alternately, so the effective issue rate is 1 instruction every clock cycle
Machine objects	Vector Instruction	PTX Instruction	A PTX instruction of a SIMD Thread is broadcast to all SIMD Lanes, so it is similar to a vector instruction
	Gather/Scatter	Global load/store (ld.global/st.global)	All GPU loads and stores are gather and scatter, in that each SIMD Lane sends a unique address. It's up to the GPU Coalescing Unit to get unit-stride performance when addresses from the SIMD Lanes allow it
	Mask Registers	Predicate Registers and Internal Mask Registers	Vector mask registers are explicitly part of the architectural state, while GPU mask registers are internal to the hardware. The GPU conditional hardware adds a new feature beyond predicate registers to manage masks dynamically
Processing and memory hardware	Vector Processor	Multithreaded SIMD Processor	These are similar, but SIMD Processors tend to have many lanes, taking a few clock cycles per lane to complete a vector, while vector architectures have few lanes and take many cycles to complete a vector. They are also multithreaded where vectors usually are not
	Control Processor	Thread Block Scheduler	The closest is the Thread Block Scheduler that assigns Thread Blocks to a multithreaded SIMD Processor. But GPUs have no scalar-vector operations and no unit-stride or strided data transfer instructions, which Control Processors often provide in vector architectures
	Scalar Processor	System Processor	Because of the lack of shared memory and the high latency to communicate over a PCI bus (1000s of clock cycles), the system processor in a GPU rarely takes on the same tasks that a scalar processor does in a vector architecture
	Vector Lane	SIMD Lane	Very similar; both are essentially functional units with registers
	Vector Registers	SIMD Lane Registers	The equivalent of a vector register is the same register in all 16 SIMD Lanes of a multithreaded SIMD Processor running a thread of SIMD instructions. The number of registers per SIMD Thread is flexible, but the maximum is 256 in Pascal, so the maximum number of vector registers is 256
	Main Memory	GPU Memory	Memory for GPU versus system memory in vector case

Figure 4.21 GPU equivalent to vector terms.

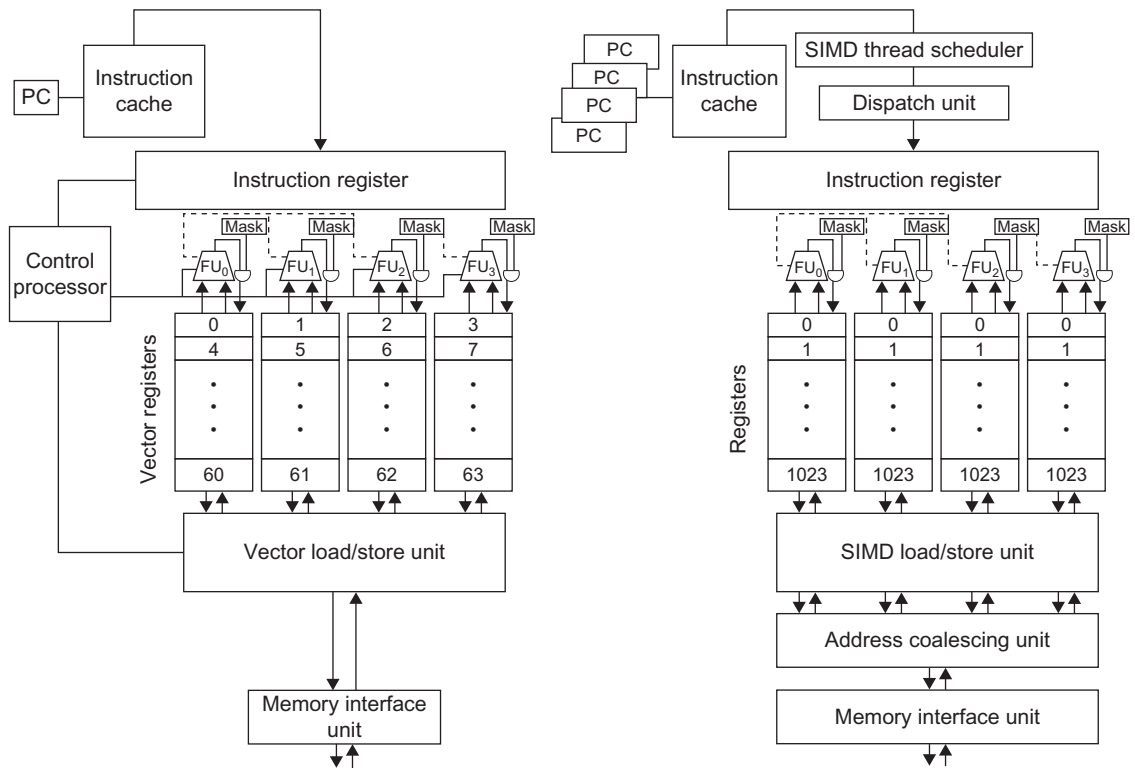

Figure 4.22 A vector processor with four lanes on the left and a multithreaded SIMD Processor of a GPU with four SIMD Lanes on the right. (GPUs typically have 16 or 32 SIMD Lanes.) The Control Processor supplies scalar operands for scalar-vector operations, increments addressing for unit and nonunit stride accesses to memory, and performs other accounting-type operations. Peak memory performance occurs only in a GPU when the Address Coalescing Unit can discover localized addressing. Similarly, peak computational performance occurs when all internal mask bits are set identically. Note that the SIMD Processor has one PC per SIMD Thread to help with multithreading.

The closest GPU term to a vectorized loop is Grid, and a PTX instruction is the closest to a vector instruction because a SIMD Thread broadcasts a PTX instruction to all SIMD Lanes.

With respect to memory access instructions in the two architectures, all GPU loads are gather instructions and all GPU stores are scatter instructions. If data addresses of CUDA Threads refer to nearby addresses that fall into the same cache/memory block at the same time, the Address Coalescing Unit of the GPU will ensure high memory bandwidth. The *explicit* unit-stride load and store instructions of vector architectures versus the *implicit* unit stride of GPU programming is why writing efficient GPU code requires that programmers think in terms of SIMD operations, even though the CUDA programming model looks like MIMD. Because CUDA Threads can generate their own addresses, strided as well as gather-scatter, addressing vectors are found in both vector architectures and GPUs.

As we mentioned several times, the two architectures take very different approaches to hiding memory latency. Vector architectures amortize it across all the elements of the vector by having a deeply pipelined access, so you pay the latency only once per vector load or store. Therefore vector loads and stores are like a block transfer between memory and the vector registers. In contrast, GPUs hide memory latency using multithreading. (Some researchers are investigating adding multithreading to vector architectures to try to capture the best of both worlds.)

With respect to conditional branch instructions, both architectures implement them using mask registers. Both conditional branch paths occupy time and/or space even when they do not store a result. The difference is that the vector compiler manages mask registers explicitly in software while the GPU hardware and assembler manages them implicitly using branch synchronization markers and an internal stack to save, complement, and restore masks.

The Control Processor of a vector computer plays an important role in the execution of vector instructions. It broadcasts operations to all the Vector Lanes and broadcasts a scalar register value for vector-scalar operations. It also does implicit calculations that are explicit in GPUs, such as automatically incrementing memory addresses for unit-stride and nonunit-stride loads and stores. The Control Processor is missing in the GPU. The closest analogy is the Thread Block Scheduler, which assigns Thread Blocks (bodies of vector loop) to multithreaded SIMD Processors. The runtime hardware mechanisms in a GPU that both generate addresses and then discover if they are adjacent, which is commonplace in many DLP applications, are likely less power-efficient than using a Control Processor.

The scalar processor in a vector computer executes the scalar instructions of a vector program; that is, it performs operations that would be too slow to do in the vector unit. Although the system processor that is associated with a GPU is the closest analogy to a scalar processor in a vector architecture, the separate address spaces plus transferring over a PCIe bus means thousands of clock cycles of overhead to use them together. The scalar processor can be slower than a vector processor for floating-point computations in a vector computer, but not by the same ratio as the system processor versus a multithreaded SIMD Processor (given the overhead).

Therefore each “vector unit” in a GPU must do computations that you would expect to do using a scalar processor in a vector computer. That is, rather than calculate on the system processor and communicate the results, it can be faster to disable all but one SIMD Lane using the predicate registers and built-in masks and do the scalar work with one SIMD Lane. The relatively simple scalar processor in a vector computer is likely to be faster and more power-efficient than the GPU solution. If system processors and GPUs become more closely tied together in the future, it will be interesting to see if system processors can play the same role as scalar processors do for vector and multimedia SIMD architectures.

Similarities and Differences Between Multimedia SIMD Computers and GPUs

At a high level, multicore computers with multimedia SIMD instruction extensions do share similarities with GPUs. [Figure 4.23](#) summarizes the similarities and differences.

Both are multiprocessors whose processors use multiple SIMD Lanes, although GPUs have more processors and many more lanes. Both use hardware multithreading to improve processor utilization, although GPUs have hardware support for many more threads. Both have roughly 2:1 performance ratios between peak performance of single-precision and double-precision floating-point arithmetic. Both use caches, although GPUs use smaller streaming caches, and multicore computers use large multilevel caches that try to contain whole working sets completely. Both use a 64-bit address space, although the physical main memory is much smaller in GPUs. Both support memory protection at the page level as well as demand paging, which allows them to address far more memory than they have on board.

In addition to the large numerical differences in processors, SIMD Lanes, hardware thread support, and cache sizes, there are many architectural differences. The scalar processor and multimedia SIMD instructions are tightly integrated in traditional computers; they are separated by an I/O bus in GPUs, and they even have separate main memories. The multiple SIMD Processors in a GPU use a single address space and can support a coherent view of all memory on some systems given support from CPU vendors (such as the IBM Power9). Unlike GPUs, multimedia SIMD instructions historically did not support gather-scatter memory accesses, which [Section 4.7](#) shows is a significant omission.

Feature	Multicore with SIMD	GPU
SIMD Processors	4–8	8–32
SIMD Lanes/Processor	2–4	up to 64
Multithreading hardware support for SIMD Threads	2–4	up to 64
Typical ratio of single-precision to double-precision performance	2:1	2:1
Largest cache size	40 MB	4 MB
Size of memory address	64-bit	64-bit
Size of main memory	up to 1024 GB	up to 24 GB
Memory protection at level of page	Yes	Yes
Demand paging	Yes	Yes
Integrated scalar processor/SIMD Processor	Yes	No
Cache coherent	Yes	Yes on some systems

Figure 4.23 Similarities and differences between multicore with multimedia SIMD extensions and recent GPUs.

Summary

Now that the veil has been lifted, we can see that GPUs are really just multi-threaded SIMD Processors, although they have more processors, more lanes per processor, and more multithreading hardware than do traditional multicore computers. For example, the Pascal P100 GPU has 56 SIMD Processors with 64 lanes per processor and hardware support for 64 SIMD Threads. Pascal embraces instruction-level parallelism by issuing instructions from two SIMD Threads to two sets of SIMD Lanes. GPUs also have less cache memory—Pascal’s L2 cache is 4 MiB—and it can be coherent with a cooperative distant scalar processor or distant GPUs.

The CUDA programming model wraps up all these forms of parallelism around a single abstraction, the CUDA Thread. Thus the CUDA programmer can think of programming thousands of threads, although they are really executing each block of 32 threads on the many lanes of the many SIMD Processors. The CUDA programmer who wants good performance keeps in mind that these threads are organized in blocks and executed 32 at a time and that addresses need to be to adjacent addresses to get good performance from the memory system.

Although we’ve used CUDA and the NVIDIA GPU in this section, rest assured that the same ideas are found in the OpenCL programming language and in GPUs from other companies.

Now that you understand better how GPUs work, we reveal the real jargon. [Figures 4.24](#) and [4.25](#) match the descriptive terms and definitions of this section with the official CUDA/NVIDIA and AMD terms and definitions. We also include the OpenCL terms. We believe the GPU learning curve is steep in part because of using terms such as “streaming multiprocessor” for the SIMD Processor, “thread processor” for the SIMD Lane, and “shared memory” for local memory—especially because local memory is *not* shared between SIMD Processors! We hope that this two-step approach gets you up that curve quicker, even if it’s a bit indirect.

4.5

Detecting and Enhancing Loop-Level Parallelism

Loops in programs are the fountainhead of many of the types of parallelism we previously discussed here and in [Chapter 5](#). In this section, we discuss compiler technology used for discovering the amount of parallelism that we can exploit in a program as well as hardware support for these compiler techniques. We define precisely when a loop is parallel (or vectorizable), how a dependence can prevent a loop from being parallel, and techniques for eliminating some types of dependences. Finding and manipulating loop-level parallelism is critical to exploiting both DLP and TLP, as well as the more aggressive static ILP approaches (e.g., VLIW) that we examine in Appendix H.

Type	More descriptive name used in this book	Official CUDA/NVIDIA term	Short explanation and AMD and OpenCL terms	Official CUDA/NVIDIA definition
Program abstractions	Vectorizable loop	Grid	A vectorizable loop, executed on the GPU, made up of one or more “Thread Blocks” (or bodies of vectorized loop) that can execute in parallel. OpenCL name is “index range.” AMD name is “NDRange”	A Grid is an array of Thread Blocks that can execute concurrently, sequentially, or a mixture
	Body of Vectorized loop	Thread Block	A vectorized loop executed on a multithreaded SIMD Processor, made up of one or more threads of SIMD instructions. These SIMD Threads can communicate via local memory. AMD and OpenCL name is “work group”	A Thread Block is an array of CUDA Threads that execute concurrently and can cooperate and communicate via shared memory and barrier synchronization. A Thread Block has a Thread Block ID within its Grid
	Sequence of SIMD Lane operations	CUDA Thread	A vertical cut of a thread of SIMD instructions corresponding to one element executed by one SIMD Lane. Result is stored depending on mask. AMD and OpenCL call a CUDA Thread a “work item”	A CUDA Thread is a lightweight thread that executes a sequential program and that can cooperate with other CUDA Threads executing in the same Thread Block. A CUDA Thread has a thread ID within its Thread Block
Machine object	A thread of SIMD instructions	Warp	A traditional thread, but it contains just SIMD instructions that are executed on a multithreaded SIMD Processor. Results are stored depending on a per-element mask. AMD name is “wavefront”	A warp is a set of parallel CUDA Threads (e.g., 32) that execute the same instruction together in a multithreaded SIMT/SIMD Processor
	SIMD instruction	PTX instruction	A single SIMD instruction executed across the SIMD Lanes. AMD name is “AMDIL” or “FSAIL” instruction	A PTX instruction specifies an instruction executed by a CUDA Thread

Figure 4.24 Conversion from terms used in this chapter to official NVIDIA/CUDA and AMD jargon. OpenCL names are given in the book’s definitions.

Loop-level parallelism is normally investigated at the source level or close to it, while most analysis of ILP is done once instructions have been generated by the compiler. Loop-level analysis involves determining what dependences exist among the operands in a loop across the iterations of that loop. For now, we will consider only data dependences, which arise when an operand is written at some point and read at a later point. Name dependences also exist and may be removed by the renaming techniques discussed in [Chapter 3](#).

The analysis of loop-level parallelism focuses on determining whether data accesses in later iterations are dependent on data values produced in earlier iterations; such dependence is called a *loop-carried dependence*. Most of the examples

Type	More descriptive name used in this book	Official CUDA/NVIDIA term	Short explanation and AMD and OpenCL terms	Official CUDA/NVIDIA definition
Processing hardware	Multithreaded SIMD processor	Streaming multiprocessor	Multithreaded SIMD Processor that executes thread of SIMD instructions, independent of other SIMD Processors. Both AMD and OpenCL call it a “compute unit.” However, the CUDA programmer writes program for one lane rather than for a “vector” of multiple SIMD Lanes	A streaming multiprocessor (SM) is a multithreaded SIMT/SIMD Processor that executes warps of CUDA Threads. A SIMT program specifies the execution of one CUDA Thread, rather than a vector of multiple SIMD Lanes
	Thread Block Scheduler	Giga Thread Engine	Assigns multiple bodies of vectorized loop to multithreaded SIMD Processors. AMD name is “Ultra-Threaded Dispatch Engine”	Distributes and schedules Thread Blocks of a grid to streaming multiprocessors as resources become available
	SIMD Thread scheduler	Warp scheduler	Hardware unit that schedules and issues threads of SIMD instructions when they are ready to execute; includes a scoreboard to track SIMD Thread execution. AMD name is “Work Group Scheduler”	A warp scheduler in a streaming multiprocessor schedules warps for execution when their next instruction is ready to execute
	SIMD Lane	Thread processor	Hardware SIMD Lane that executes the operations in a thread of SIMD instructions on a single element. Results are stored depending on mask. OpenCL calls it a “processing element.” AMD name is also “SIMD Lane”	A thread processor is a datapath and register file portion of a streaming multiprocessor that executes operations for one or more lanes of a warp
Memory hardware	GPU Memory	Global memory	DRAM memory accessible by all multithreaded SIMD Processors in a GPU. OpenCL calls it “global memory”	Global memory is accessible by all CUDA Threads in any Thread Block in any grid; implemented as a region of DRAM, and may be cached
	Private memory	Local memory	Portion of DRAM memory private to each SIMD Lane. Both AMD and OpenCL call it “private memory”	Private “thread-local” memory for a CUDA Thread; implemented as a cached region of DRAM
	Local memory	Shared memory	Fast local SRAM for one multithreaded SIMD Processor, unavailable to other SIMD Processors. OpenCL calls it “local memory.” AMD calls it “group memory”	Fast SRAM memory shared by the CUDA Threads composing a Thread Block, and private to that Thread Block. Used for communication among CUDA Threads in a Thread Block at barrier synchronization points
	SIMD Lane registers	Registers	Registers in a single SIMD Lane allocated across body of vectorized loop. AMD also calls them “registers”	Private registers for a CUDA Thread; implemented as multithreaded register file for certain lanes of several warps for each thread processor

Figure 4.25 Conversion from terms used in this chapter to official NVIDIA/CUDA and AMD jargon. Note that our descriptive terms “local memory” and “private memory” use the OpenCL terminology. NVIDIA uses SIMT (single-instruction multiple-thread) rather than SIMD to describe a streaming multiprocessor. SIMT is preferred over SIMD because the per-thread branching and control flow are unlike any SIMD machine.

we considered in Chapters 2 and 3 had no loop-carried dependences and thus are loop-level parallel. To see that a loop is parallel, let us first look at the source representation:

```
for (i=999; i>=0; i=i-1)
    x[i] = x[i] + s;
```

In this loop, the two uses of $x[i]$ are dependent, but this dependence is within a single iteration and is not loop-carried. There is a loop-carried dependence between successive uses of i in different iterations, but this dependence involves an induction variable that can be easily recognized and eliminated. We saw examples of how to eliminate dependences involving induction variables during loop unrolling in Section 2.2 of Chapter 2, and we will look at additional examples later in this section.

Because finding loop-level parallelism involves recognizing structures such as loops, array references, and induction variable computations, a compiler can do this analysis more easily at or near the source level, in contrast to the machine-code level. Let's look at a more complex example.

Example Consider a loop like this one:

```
for (i=0; i<100; i=i+1) {
    A[i+1] = A[i] + C[i]; /* S1 */
    B[i+1] = B[i] + A[i+1]; /* S2 */
}
```

Assume that A , B , and C are distinct, nonoverlapping arrays. (In practice, the arrays may sometimes be the same or may overlap. Because the arrays may be passed as parameters to a procedure that includes this loop, determining whether arrays overlap or are identical often requires sophisticated, interprocedural analysis of the program.) What are the data dependences among the statements $S1$ and $S2$ in the loop?

Answer There are two different dependences:

1. $S1$ uses a value computed by $S1$ in an earlier iteration, because iteration i computes $A[i+1]$, which is read in iteration $i+1$. The same is true of $S2$ for $B[i]$ and $B[i+1]$.
2. $S2$ uses the value $A[i+1]$ computed by $S1$ in the same iteration.

These two dependences are distinct and have different effects. To see how they differ, let's assume that only one of these dependences exists at a time. Because the dependence of statement $S1$ is on an earlier iteration of $S1$, this dependence is loop-carried. This dependence forces successive iterations of this loop to execute in series.

The second dependence (S2 depending on S1) is within an iteration and is not loop-carried. Thus, if this were the only dependence, multiple iterations of the loop would execute in parallel, as long as each pair of statements in an iteration were kept in order. We saw this type of dependence in an example in Section 2.2, where unrolling could expose the parallelism. These intra-loop dependences are common; for example, a sequence of vector instructions that uses chaining exhibits exactly this sort of dependence.

It is also possible to have a loop-carried dependence that does not prevent parallelism, as the next example shows.

Example Consider a loop like this one:

```
for (i=0; i<100; i=i+1) {
    A[i] = A[i] + B[i];    /* S1 */
    B[i+1] = C[i] + D[i]; /* S2 */
}
```

What are the dependences between S1 and S2? Is this loop parallel? If not, show how to make it parallel.

Answer Statement S1 uses the value assigned in the previous iteration by statement S2, so there is a loop-carried dependence between S2 and S1. Despite this loop-carried dependence, this loop can be made parallel. Unlike the earlier loop, this dependence is not circular; neither statement depends on itself, and although S1 depends on S2, S2 does not depend on S1. A loop is parallel if it can be written without a cycle in the dependences because the absence of a cycle means that the dependences give a partial ordering on the statements.

Although there are no circular dependences in the preceding loop, it must be transformed to conform to the partial ordering and expose the parallelism. Two observations are critical to this transformation:

1. There is no dependence from S1 to S2. If there were, then there would be a cycle in the dependences and the loop would not be parallel. Because this other dependence is absent, interchanging the two statements will not affect the execution of S2.
2. On the first iteration of the loop, statement S2 depends on the value of B[0] computed *prior* to initiating the loop.

These two observations allow us to replace the preceding loop with the following code sequence:

```
A[0] = A[0] + B[0];
for (i=0; i<99; i=i+1) {
```

```

        B[i+1] = C[i] + D[i];
        A[i+1] = A[i+1] + B[i+1];
    }
    B[100] = C[99] + D[99];

```

The dependence between the two statements is no longer loop-carried so that iterations of the loop may be overlapped, provided the statements in each iteration are kept in order.

Our analysis needs to begin by finding all loop-carried dependences. This dependence information is *inexact*, in the sense that it tells us that such dependence *may* exist. Consider the following example:

```

for (i=0; i<100; i=i+1) {
    A[i] = B[i] + C[i]
    D[i] = A[i] * E[i]
}

```

The second reference to A in this example need not be translated to a load instruction because we know that the value is computed and stored by the previous statement. Thus the second reference to A can simply be a reference to the register into which A was computed. Performing this optimization requires knowing that the two references are *always* to the same memory address and that there is no intervening access to the same location. Normally, data dependence analysis tells that only one reference *may* depend on another; a more complex analysis is required to determine that two references *must be* to the exact same address. In the preceding example, a simple version of this analysis suffices because the two references are in the same basic block.

Often loop-carried dependences are in the form of a *recurrence*. A recurrence occurs when a variable is defined based on the value of that variable in an earlier iteration, usually the one immediately preceding, as in the following code fragment:

```

for (i=1; i<100; i=i+1) {
    Y[i] = Y[i-1] + Y[i];
}

```

Detecting a recurrence can be important for two reasons: some architectures (especially vector computers) have special support for executing recurrences, and in an ILP context, it may still be possible to exploit a fair amount of parallelism.

Finding Dependences

Clearly, finding the dependences in a program is important both to determine which loops might contain parallelism and to eliminate name dependences. The complexity of dependence analysis arises also because of the presence of arrays

and pointers in languages such as C or C++, or pass-by-reference parameter passing in Fortran. Because scalar variable references explicitly refer to a name, they can usually be analyzed quite easily with aliasing because of pointers and reference parameters causing some complications and uncertainty in the analysis.

How does the compiler detect dependences in general? Nearly all dependence analysis algorithms work on the assumption that array indices are *affine*. In simplest terms, a one-dimensional array index is affine if it can be written in the form $a \times i + b$, where a and b are constants and i is the loop index variable. The index of a multidimensional array is affine if the index in each dimension is affine. Sparse array accesses, which typically have the form $x[y[i]]$, are one of the major examples of nonaffine accesses.

Determining whether there is a dependence between two references to the same array in a loop is thus equivalent to determining whether two affine functions can have the identical value for different indices between the bounds of the loop. For example, suppose we have stored to an array element with index value $a \times i + b$ and loaded from the same array with index value $c \times i + d$, where i is the for-loop index variable that runs from m to n . A dependence exists if two conditions hold:

1. There are two iteration indices, j and k , that are both within the limits of the for-loop. That is, $m \leq j \leq n$, $m \leq k \leq n$.
2. The loop stores into an array element indexed by $a \times j + b$ and later fetches from that *same* array element when it is indexed by $c \times k + d$, that is, $a \times j + b = c \times k + d$.

In general, we cannot determine whether dependence exists at compile time. For example, the values of a , b , c , and d may not be known (they could be values in other arrays), making it impossible to tell if a dependence exists. In other cases, the dependence testing may be very expensive but decidable at compile time; for example, the accesses may depend on the iteration indices of multiple nested loops. Many programs, however, contain primarily simple indices where a , b , c , and d are all constants. For these cases, it is possible to devise reasonable compile time tests for dependence.

As an example, a simple and sufficient test for the absence of a dependence is the *greatest common divisor* (GCD) test. It is based on the observation that if a loop-carried dependence exists, then $\text{GCD}(c, a)$ must divide $(d - b)$. (Recall that an integer, x , *divides* another integer, y , if we get an integer quotient when we do the division y/x and there is no remainder.)

Example Use the GCD test to determine whether dependences exist in the following loop:

```
for (i=0; i<100; i=i+1) {
    X[2*i+3] = X[2*i] * 5.0;
}
```

Answer Given the values $a=2$, $b=3$, $c=2$, and $d=0$, then $\text{GCD}(a, c)=2$, and $d - b = -3$. Because 2 does not divide -3 , no dependence is possible.

The GCD test is sufficient to guarantee that no dependence exists; however, there are cases where the GCD test succeeds but no dependence exists. This can arise, for example, because the GCD test does not consider the loop bounds.

In general, determining whether a dependence actually exists is NP-complete. In practice, however, many common cases can be analyzed precisely at low cost. Recently, approaches using a hierarchy of exact tests increasing in generality and cost have been shown to be both accurate and efficient. (A test is *exact* if it precisely determines whether a dependence exists. Although the general case is NP-complete, there exist exact tests for restricted situations that are much cheaper.)

In addition to detecting the presence of a dependence, a compiler wants to classify the type of dependence. This classification allows a compiler to recognize name dependences and eliminate them at compile time by renaming and copying.

Example The following loop has multiple types of dependences. Find all the true dependences, output dependences, and antidependences, and eliminate the output dependences and antidependences by renaming.

```
for (i=0; i<100; i=i+1) {
    Y[i] = X[i] / c; /* S1 */
    X[i] = X[i] + c; /* S2 */
    Z[i] = Y[i] + c; /* S3 */
    Y[i] = c - Y[i]; /* S4 */
}
```

Answer The following dependences exist among the four statements:

1. There are true dependences from S1 to S3 and from S1 to S4 because of Y[i]. These are not loop-carried, so they do not prevent the loop from being considered parallel. These dependences will force S3 and S4 to wait for S1 to complete.
2. There is an antidependence from S1 to S2, based on X[i].
3. There is an antidependence from S3 to S4 for Y[i].
4. There is an output dependence from S1 to S4, based on Y[i].

The following version of the loop eliminates these false (or pseudo) dependences.

```
for (i=0; i<100; i=i+1) {
    T[i] = X[i] / c; /* Y renamed to T to remove output
dependence */
    X1[i] = X[i] + c; /* X renamed to X1 to remove
antidependence */
    Z[i] = T[i] + c; /* Y renamed to T to remove
antidependence */
    Y[i] = c - T[i];
}
```

After the loop, the variable `X` has been renamed `X1`. In code that follows the loop, the compiler can simply replace the name `X` by `X1`. In this case, renaming does not require an actual copy operation, as it can be done by substituting names or by register allocation. In other cases, however, renaming will require copying.

Dependence analysis is a critical technology for exploiting parallelism, as well as for the transformation-like blocking that [Chapter 2](#) covers. For detecting loop-level parallelism, dependence analysis is the basic tool. Effectively compiling programs for vector computers, SIMD computers, or multiprocessors depends critically on this analysis. The major drawback of dependence analysis is that it applies only under a limited set of circumstances, namely, among references within a single loop nest and using affine index functions. Thus there are many situations where array-oriented dependence analysis *cannot* tell us what we want to know; for example, analyzing accesses done with pointers, rather than with array indices can be much harder. (This is one reason why Fortran is still preferred over C and C++ for many scientific applications designed for parallel computers.) Similarly, analyzing references across procedure calls is extremely difficult. Thus, while analysis of code written in sequential languages remains important, we also need approaches such as OpenMP and CUDA that write explicitly parallel loops.

Eliminating Dependent Computations

As previously mentioned, one of the most important forms of dependent computations is a recurrence. A dot product is a perfect example of a recurrence:

```
for (i=9999; i>=0; i=i-1)
    sum = sum + x[i] * y[i];
```

This loop is not parallel because it has a loop-carried dependence on the variable `sum`. We can, however, transform it to a set of loops, one of which is completely parallel and the other partly parallel. The first loop will execute the completely parallel portion of this loop. It looks like this:

```
for (i=9999; i>=0; i=i-1)
    sum[i] = x[i] * y[i];
```

Notice that `sum` has been expanded from a scalar into a vector quantity (a transformation called *scalar expansion*) and that this transformation makes this new loop completely parallel. When we are done, however, we need to do the reduce step, which sums up the elements of the vector. It looks like this:

```
for (i=9999; i>=0; i=i-1)
    finalsum = finalsum + sum[i];
```

Although this loop is not parallel, it has a very specific structure called a *reduction*. Reductions are common in linear algebra, and as we will see in [Chapter 6](#),

they are also a key part of the primary parallelism primitive MapReduce used in warehouse-scale computers. In general, any function can be used as a reduction operator, and common cases include operators such as max and min.

Reductions are sometimes handled by special hardware in a vector and SIMD architecture that allows the reduce step to be done much faster than it could be done in scalar mode. These work by implementing a technique similar to what can be done in a multiprocessor environment. While the general transformation works with any number of processors, suppose for simplicity we have 10 processors. In the first step of reducing the sum, each processor executes the following (with p as the processor number ranging from 0 to 9):

```
for (i=999; i>=0; i=i-1)
    finalsum[p] = finalsum[p] + sum[i+1000*p];
```

This loop, which sums up 1000 elements on each of the 10 processors, is completely parallel. A simple scalar loop can then complete the summation of the last 10 sums. Similar approaches are used in vector processors and SIMD Processors.

It is important to observe that the preceding transformation relies on associativity of addition. Although arithmetic with unlimited range and precision is associative, computer arithmetic is not associative, for either integer arithmetic, because of limited range, or floating-point arithmetic, because of both range and precision. Thus using these restructuring techniques can sometimes lead to erroneous behavior, although such occurrences are rare. For this reason, most compilers require that optimizations that rely on associativity be explicitly enabled.

4.6

Cross-Cutting Issues

Energy and DLP: Slow and Wide Versus Fast and Narrow

A fundamental power advantage of data-level parallel architectures comes from the energy equation in [Chapter 1](#). Assuming ample data-level parallelism, the performance is the same if we halve the clock rate and double the execution resources: twice the number of lanes for a vector computer, wider registers and ALUs for multimedia SIMD, and more SIMD Lanes for GPUs. If we can lower the voltage while dropping the clock rate, we can actually reduce energy as well as the power for the computation while maintaining the same peak performance. Thus GPUs tend to have lower clock rates than system processors, which rely on high clock rates for performance (see [Section 4.7](#)).

Compared to out-of-order processors, DLP processors can have simpler control logic to launch a large number of operations per clock cycle; for example, the control is identical for all lanes in vector processors, and there is no logic to decide on multiple instruction issues or speculative execution logic. They also fetch and decode far fewer instructions. Vector architectures can also make it easier to turn off unused portions of the chip. Each vector instruction explicitly describes all the resources it needs for a number of cycles when the instruction issues.

Banked Memory and Graphics Memory

Section 4.2 noted the importance of substantial memory bandwidth for vector architectures to support unit stride, nonunit stride, and gather-scatter accesses.

To achieve the highest memory performance, stacked DRAMs are used in the top-end GPUs from AMD and NVIDIA. Intel also uses stacked DRAM in its Xeon Phi product. Also known as *high bandwidth memory* (*HBM*, *HBM2*), the memory chips are stacked and placed in the same package as the processing chip. The extensive width (typically 1024–4096 data wires) provides high bandwidth, while placing the memory chips in the same package as the processor chip reduces latency and power consumption. The capacity of stacked DRAM is typically 8–32 GB.

Given all the potential demands on the memory from both the computation tasks and the graphics acceleration tasks, the memory system could see a large number of uncorrelated requests. Unfortunately, this diversity hurts memory performance. To cope, the GPU's memory controller maintains separate queues of traffic bound for different banks, waiting until there is enough traffic to justify opening a row and transferring all requested data at once. This delay improves bandwidth but stretches latency, and the controller must ensure that no processing units starve while waiting for data, for otherwise neighboring processors could become idle. Section 4.7 shows that gather-scatter techniques and memory-bank-aware access techniques can deliver substantial increases in performance versus conventional cache-based architectures.

Strided Accesses and TLB Misses

One problem with strided accesses is how they interact with the translation lookaside buffer (TLB) for virtual memory in vector architectures or GPUs. (GPUs also use TLBs for memory mapping.) Depending on how the TLB is organized and the size of the array being accessed in memory, it is even possible to get one TLB miss for every access to an element in the array! The same type of collision can happen with caches, but the performance impact is probably less.

4.7

Putting It All Together: Embedded Versus Server GPUs and Tesla Versus Core i7

Given the popularity of graphics applications, GPUs are now found in both mobile clients and traditional servers and heavy-duty desktop computers. Figure 4.26 lists the key characteristics of the NVIDIA Tegra Parker system on a chip for embedded clients, which is popular in automobiles, and the Pascal GPU for servers. GPU server engineers hope to be able to do live animation within five years after a movie is released. GPU-embedded engineers in turn want to do what a server or game console does today on their hardware within five more years.

The NVIDIA Tegra P1 has six ARMv8 cores and a smaller Pascal GPU (capable of 750 GFLOPS) and 50 GB/s of memory bandwidth. It is the key component

	NVIDIA Tegra 2	NVIDIA Tesla P100
Market	Automotive, Embedded, Console, Tablet	Desktop, server
System processor	Six-Core ARM (2 Denver2 + 4 A57)	Not applicable
System interface	Not applicable	PCI Express × 16 Gen 3
System interface bandwidth	Not applicable	16 GB/s (each direction), 32 GB/s (total)
Clock rate	1.5 GHz	1.4 GHz
SIMD multiprocessors	2	56
SIMD Lanes/SIMD multiprocessor	128	64
Memory interface	128-bit LP-DDR4	4096-bit HBM2
Memory bandwidth	50 GB/s	732 GB/s
Memory capacity	up to 16 GB	up to 16 GB
Transistors	7 billion	15.3 billion
Process	TSMC 16 nm FinFET	TSMC 16 nm FinFET
Die area	147 mm ²	645 mm ²
Power	20 W	300 W

Figure 4.26 Key features of the GPUs for embedded clients and servers.

of the NVIDIA DRIVE PX2 computing platform that is used in cars for autonomous driving. The NVIDIA Tegra X1 is the previous generation and is used in several high-end tablets, such as the Google Pixel C and the NVIDIA Shield TV. It has a Maxwell-class GPU capable of 512 GFLOPS.

The NVIDIA Tesla P100 is the Pascal GPU discussed extensively in this chapter. (Tesla is Nvidia's name for products targeting general-purpose computing.) The clock rate is 1.4 GHz, and it includes 56 SIMD Processors. The path to HBM2 memory is 4096-bits wide, and it transfers data on both the rising and falling edge of a 0.715 GHz clock, which means a peak memory bandwidth of 732 GB/s. It connects to the host system processor and memory via a PCI Express × 16 Gen 3 link, which has a peak bidirectional rate of 32 GB/s.

All physical characteristics of the P100 die are impressively large: it contains 15.3 billion transistors, the die size is 645 mm² in a 16-nm TSMC process, and the typical power is 300 W.

Comparison of a GPU and a MIMD With Multimedia SIMD

A group of Intel researchers published a paper ([Lee et al., 2010](#)) comparing a quad-core Intel i7 with multimedia SIMD extensions to the Tesla GTX 280. Although the study did not compare the latest versions of CPUs and GPUs, it was the most

	Core i7-960	GTX 280	Ratio 280/i7
Number of processing elements (cores or SMs)	4	30	7.5
Clock frequency (GHz)	3.2	1.3	0.41
Die size	263	576	2.2
Technology	Intel 45 nm	TSMC 65 nm	1.6
Power (chip, not module)	130	130	1.0
Transistors	700 M	1400 M	2.0
Memory bandwidth (GB/s)	32	141	4.4
Single-precision SIMD width	4	8	2.0
Double-precision SIMD width	2	1	0.5
Peak single-precision scalar FLOPS (GFLOP/S)	26	117	4.6
Peak single-precision SIMD FLOPS (GFLOP/S)	102	311–933	3.0–9.1
(SP 1 add or multiply)	N.A.	(311)	(3.0)
(SP 1 instruction fused multiply-adds)	N.A.	(622)	(6.1)
(Rare SP dual issue fused multiply-add and multiply)	N.A.	(933)	(9.1)
Peak double-precision SIMD FLOPS (GFLOP/S)	51	78	1.5

Figure 4.27 Intel Core i7-960 and NVIDIA GTX 280. The rightmost column shows the ratios of GTX 280 to Core i7. For single-precision SIMD FLOPS on the GTX 280, the higher speed (933) comes from a very rare case of dual issuing of fused multiply-add and multiply. More reasonable is 622 for single fused multiply-adds. Note that these memory bandwidths are higher than in Figure 4.28 because these are DRAM pin bandwidths and those in Figure 4.28 are at the processors as measured by a benchmark program. From Table 2 in Lee, W.V., et al., 2010. Debunking the $100 \times$ GPU vs. CPU myth: an evaluation of throughput computing on CPU and GPU. In: Proc. 37th Annual Int'l. Symposium on Computer Architecture (ISCA), June 19–23, 2010, Saint-Malo, France.

in-depth comparison of the two styles in that it explained the reasons behind the differences in performance. Moreover, the current versions of these architectures share many similarities to the ones in the study.

Figure 4.27 lists the characteristics of the two systems. Both products were purchased in the fall of 2009. The Core i7 is in Intel's 45-nanometer semiconductor technology, while the GPU is in TSMC's 65-nanometer technology. Although it might have been fairer to have a comparison done by a neutral party or by both interested parties, the purpose of this section is *not* to determine how much faster one product is than the other, but to try to understand the relative value of features of these two contrasting architecture styles.

The rooflines of the Core i7 920 and GTX 280 in Figure 4.28 illustrate the differences in the computers. The 920 has a slower clock rate than the 960 (2.66 GHz vs. 3.2 GHz), but the rest of the system is the same. Not only does the GTX 280 have much higher memory bandwidth and double-precision floating-point performance, but also its double-precision ridge point is considerably to the left. As previously mentioned, it is much easier to hit peak computational performance the further the ridge point of the roofline is to the left. The double-precision ridge point

Figure 4.28 Roofline model (Williams et al. 2009). These rooflines show double-precision floating-point performance in the top row and single-precision performance in the bottom row. (The DP FP performance ceiling is also in the bottom row to give perspective.) The Core i7 920 on the left has a peak DP FP performance of 42.66 GFLOP/s, a SP FP peak of 85.33 GFLOP/s, and a peak memory bandwidth of 16.4 GB/s. The NVIDIA GTX 280 has a DP FP peak of 78 GFLOP/s, SP FP peak of 624 GFLOP/s, and 127 GB/s of memory bandwidth. The dashed vertical line on the left represents an arithmetic intensity of 0.5 FLOP/byte. It is limited by memory bandwidth to no more than 8 DP GFLOP/s or 8 SP GFLOP/s on the Core i7. The dashed vertical line to the right has an arithmetic intensity of 4 FLOP/byte. It is limited only computationally to 42.66 DP GFLOP/s and 64 SP GFLOP/s on the Core i7 and to 78 DP GFLOP/s and 512 DP GFLOP/s on the GTX 280. To hit the highest computation rate on the Core i7, you need to use all 4 cores and SSE instructions with an equal number of multiplies and adds. For the GTX 280, you need to use fused multiply-add instructions on all multithreaded SIMD Processors.

is 0.6 for the GTX 280 versus 2.6 for the Core i7. For single-precision performance, the ridge point moves far to the right, as it's considerably harder to hit the roof of single-precision performance because it is so much higher. Note that the arithmetic intensity of the kernel is based on the bytes that go to main memory, not the bytes that go to cache memory. Thus caching can change the arithmetic intensity of a kernel on a particular computer, presuming that most references really go to the cache. The Rooflines help explain the relative performance in this case study. Note also that this bandwidth is for unit-stride accesses in both architectures. Real gather-scatter addresses that are not coalesced are slower on the GTX 280 and on the Core i7, as we will see.

The researchers said that they selected the benchmark programs by analyzing the computational and memory characteristics of four recently proposed benchmark suites and then “formulated the set of *throughput computing kernels* that capture these characteristics.” Figure 4.29 describes these 14 kernels, and Figure 4.30 shows the performance results, with larger numbers meaning faster.

Given that the raw performance specifications of the GTX 280 vary from $2.5 \times$ slower (clock rate) to $7.5 \times$ faster (cores per chip) while the performance varies from $2.0 \times$ slower (Solv) to $15.2 \times$ faster (GJK), the Intel researchers explored the reasons for the differences:

- *Memory bandwidth.* The GPU has $4.4 \times$ the memory bandwidth, which helps explain why LBM and SAXPY run 5.0 and $5.3 \times$ faster; their working sets are hundreds of megabytes and thus don't fit into the Core i7 cache. (To access memory intensively, they did not use cache blocking on SAXPY.) Thus the slope of the rooflines explains their performance. SpMV also has a large working set, but it only runs $1.9 \times$ because the double-precision floating point of the GTX 280 is just $1.5 \times$ faster than the Core i7.
- *Compute bandwidth.* Five of the remaining kernels are compute bound: SGEMM, Conv, FFT, MC, and Bilat. The GTX is faster by 3.9, 2.8, 3.0, 1.8, and 5.7, respectively. The first three of these use single-precision floating-point arithmetic, and GTX 280 single-precision is $3\text{--}6 \times$ faster. (The $9 \times$ faster than the Core i7 as shown in Figure 4.27 occurs only in the very special case when the GTX 280 can issue a fused multiply-add and a multiply per clock cycle.) MC uses double-precision, which explains why it's just $1.8 \times$ faster since DP performance is only $1.5 \times$ faster. Bilat uses transcendental functions, which the GTX 280 supports directly (see Figure 4.17). The Core i7 spends two-thirds of its time calculating transcendental functions, so the GTX 280 is $5.7 \times$ faster. This observation helps point out the value of hardware support for operations that occur in your workload: double-precision floating-point and perhaps even transcendentals.
- *Cache benefits.* Ray casting (RC) is only $1.6 \times$ faster on the GTX because cache blocking with the Core i7 caches prevents it from becoming memory bandwidth bound, as it is on GPUs. Cache blocking can help Search, too. If the index trees are small so that they fit into the cache, the Core i7 is twice

Kernel	Application	SIMD	TLP	Characteristics
SGEMM (SGEMM)	Linear algebra	Regular	Across 2D tiles	Compute bound after tiling
Monte Carlo (MC)	Computational finance	Regular	Across paths	Compute bound
Convolution (Conv)	Image analysis	Regular	Across pixels	Compute bound; BW bound for small filters
FFT (FFT)	Signal processing	Regular	Across smaller FFTs	Compute bound or BW bound depending on size
SAXPY (SAXPY)	Dot product	Regular	Across vector	BW bound for large vectors
LBM (LBM)	Time migration	Regular	Across cells	BW bound
Constraint solver (Solv)	Rigid body physics	Gather/Scatter	Across constraints	Synchronization bound
SpMV (SpMV)	Sparse solver	Gather	Across nonzero	BW bound for typical large matrices
GJK (GJK)	Collision detection	Gather/Scatter	Across objects	Compute bound
Sort (Sort)	Database	Gather/Scatter	Across elements	Compute bound
Ray casting (RC)	Volume rendering	Gather	Across rays	4–8 MB first level working set; over 500 MB last level working set
Search (Search)	Database	Gather/Scatter	Across queries	Compute bound for small tree, BW bound at bottom of tree for large tree
Histogram (Hist)	Image analysis	Requires conflict detection	Across pixels	Reduction/synchronization bound
Bilateral (Bilat)	Image analysis	Regular	Across pixels	Compute bound

Figure 4.29 Throughput computing kernel characteristics. The name in parentheses identifies the benchmark name in this section. The authors suggest that code for both machines had equal optimization effort. From Table 1 in Lee, W.V., et al., 2010. Debunking the $100\times$ GPU vs. CPU myth: an evaluation of throughput computing on CPU and GPU. In: Proc. 37th Annual Int'l. Symposium on Computer Architecture (ISCA), June 19–23, 2010, Saint-Malo, France.

as fast. Larger index trees make them memory bandwidth bound. Overall, the GTX 280 runs Search $1.8\times$ faster. Cache blocking also helps Sort. While most programmers wouldn't run Sort on a SIMD Processor, it can be written with a 1-bit Sort primitive called *split*. However, the split algorithm executes many more instructions than a scalar sort does. As a result, the GTX 280 runs only $0.8\times$ as fast as the Core i7. Note that caches also help other kernels on the Core i7 because cache blocking allows SGEMM, FFT, and SpMV to become

Kernel	Units	Core i7-960	GTX 280	GTX 280/ i7-960
SGEMM	GFLOP/s	94	364	3.9
MC	Billion paths/s	0.8	1.4	1.8
Conv	Million pixels/s	1250	3500	2.8
FFT	GFLOP/s	71.4	213	3.0
SAXPY	GB/s	16.8	88.8	5.3
LBM	Million lookups/s	85	426	5.0
Solv	Frames/s	103	52	0.5
SpMV	GFLOP/s	4.9	9.1	1.9
GJK	Frames/s	67	1020	15.2
Sort	Million elements/s	250	198	0.8
RC	Frames/s	5	8.1	1.6
Search	Million queries/s	50	90	1.8
Hist	Million pixels/s	1517	2583	1.7
Bilat	Million pixels/s	83	475	5.7

Figure 4.30 Raw and relative performance measured for the two platforms. In this study, SAXPY is used only as a measure of memory bandwidth, so the right unit is GB/s and not GFLOP/s. Based on Table 3 in Lee, W.V., et al., 2010. Debunking the $100\times$ GPU vs. CPU myth: an evaluation of throughput computing on CPU and GPU. In: Proc. 37th Annual Int'l. Symposium on Computer Architecture (ISCA), June 19–23, 2010, Saint-Malo, France.

compute bound. This observation reemphasizes the importance of cache blocking optimizations in [Chapter 2](#).

- *Gather-Scatter.* The multimedia SIMD extensions are of little help if the data are scattered throughout main memory; optimal performance comes only when data are aligned on 16-byte boundaries. Thus GJK gets little benefit from SIMD on the Core i7. As previously mentioned, GPUs offer gather-scatter addressing that is found in a vector architecture but omitted from SIMD extensions. The Address Coalescing Unit helps as well by combining accesses to the same DRAM line, thereby reducing the number of gathers and scatters. The memory controller also batches together accesses to the identical DRAM page. This combination means the GTX 280 runs GJK a startling $15.2\times$ faster than the Core i7, which is larger than any single physical parameter in [Figure 4.27](#). This observation reinforces the importance of gather-scatter to vector and GPU architectures that is missing from SIMD extensions.
- *Synchronization.* The performance synchronization of Hist is limited by atomic updates, which are responsible for 28% of the total runtime on the Core i7 despite its having a hardware fetch-and-increment instruction. Thus Hist is

only $1.7 \times$ faster on the GTX 280. Solv solves a batch of independent constraints in a small amount of computation followed by barrier synchronization. The Core i7 benefits from the atomic instructions and a memory consistency model that ensures the right results even if not all previous accesses to memory hierarchy have completed. Without the memory consistency model, the GTX 280 version launches some batches from the system processor, which leads to the GTX 280 running $0.5 \times$ as fast as the Core i7. This observation points out how synchronization performance can be important for some data parallel problems.

It was interesting that the gather-scatter support of vector architectures, which pre-date the SIMD instructions by decades, was so important to the effective usefulness of these SIMD extensions, which some had predicted before the comparison (Gebis and Patterson, 2007). The Intel researchers noted that 6 of the 14 kernels would exploit SIMD better with more efficient gather-scatter support on the Core i7.

Note that an important feature missing from this comparison was describing the level of effort to get the results for the two systems. Ideally, future comparisons would release the code used on both systems so that others could re-create the same experiments on different hardware platforms and possibly improve on the results.

Comparison Update

In the intervening years, the weaknesses of the Core i7 and Tesla GTX 280 have been addressed by their successors. Intel's ACV2 added gather instructions, and AVX/512 added scatter instructions, both of which are found in the Intel Skylake series. Nvidia Pascal has double-precision floating-point performance that is one-half instead of one-eighth the speed of single precision, fast atomic operations, and caches.

Figure 4.31 lists the characteristics of these two successors, Figure 4.32 compares performance using 3 of the 14 benchmarks in the original paper (those were the ones for which we could find source code), and Figure 4.33 shows the two new roofline models. The new GPU chip is 15 to 50 times faster and the new CPU chips is 50 times faster than their predecessors, and the new GPU is 2–5 times faster than the new CPU.

4.8

Fallacies and Pitfalls

While data-level parallelism is the easiest form of parallelism after ILP from the programmer's perspective, and plausibly the simplest from the architect's perspective, it still has many fallacies and pitfalls.

Fallacy *GPUs suffer from being coprocessors.*

Although the split between main memory and GPU memory has disadvantages, there are advantages to being at a distance from the CPU.

	Xeon Platinum 8180	P100	Ratio P100/Xeon
Number of processing elements (cores or SMs)	28	56	2.0
Clock frequency (GHz)	2.5	1.3	0.52
Die size	N.A.	610 mm ²	—
Technology	Intel 14 nm	TSMC 16 nm	1.1
Power (chip, not module)	80 W	300 W	3.8
Transistors	N.A.	15.3 B	—
Memory bandwidth (GB/s)	199	732	3.7
Single-precision SIMD width	16	8	0.5
Double-precision SIMD width	8	4	0.5
Peak single-precision SIMD FLOPS (GFLOP/s)	4480	10,608	2.4
Peak double-precision SIMD FLOPS (GFLOP/s)	2240	5304	2.4

Figure 4.31 Intel Xeon ?? and NVIDIA P100. The rightmost column shows the ratios of P100 to the Xeon. Note that these memory bandwidths are higher than in [Figure 4.28](#) because these are DRAM pin bandwidths and those in [Figure 4.28](#) are at the processors as measured by a benchmark program.

Kernel	Units	Xeon Platinum 8180	P100	P100/Xeon	GTX 280/i7-960
SGEMM	GFLOP/s	3494	6827	2.0	3.9
DGEMM	GFLOP/s	1693	3490	2.1	—
FFT-S	GFLOP/s	410	1820	4.4	3.0
FFT-D	GFLOP/s	190	811	4.2	—
SAXPY	GB/s	207	544	2.6	5.3
DAXPY	GB/s	212	556	2.6	—

Figure 4.32 Raw and relative performance measured for modern versions of the two platforms as compared to the relative performance of the original platforms. Like [Figure 4.30](#), SAXPY and DAXPY are used only as a measure of memory bandwidth, so the proper unit is GB/s and not GFLOP/s.

For example, PTX exists in part because of the I/O device nature of GPUs. This level of indirection between the compiler and the hardware gives GPU architects much more flexibility than system processor architects. It's often hard to know in advance whether an architecture innovation will be well supported by compilers and libraries and be important to applications. Sometimes a new mechanism will even prove useful for one or two generations and then fade in importance as the IT world changes. PTX allows GPU architects to try innovations speculatively and drop them in subsequent generations if they disappoint or fade in importance, which encourages experimentation. The justification for inclusion is understandably considerably higher for system processors—and thus much less

Figure 4.33 Roofline models of older and newer CPUs versus older and newer GPUs. The higher roofline for each computer is single-precision floating-point performance, and the lower one is double-precision performance.

experimentation can occur—as distributing binary machine code normally implies that new features must be supported by all future generations of that architecture.

A demonstration of the value of PTX is that the different generation architecture radically changed the hardware instruction set—from being memory-oriented like x86 to being register-oriented like RISC-V *as well as* doubling the address size to 64 bits—without disrupting the NVIDIA software stack.

Pitfall *Concentrating on peak performance in vector architectures and ignoring start-up overhead.*

Early memory-memory vector processors such as the TI ASC and the CDC STAR-100 had long start-up times. For some vector problems, vectors had to be longer than 100 for the vector code to be faster than the scalar code! On the CYBER 205—derived from the STAR-100—the start-up overhead for DAXPY is 158 clock cycles, which substantially increases the break-even point. If the clock rates of the Cray-1 and the CYBER 205 were identical, the Cray-1 would be faster until the vector length was greater than 64. Because the Cray-1 clock rate was also higher (even though the 205 was newer), the crossover point was a vector length over 100.

Pitfall *Increasing vector performance, without comparable increases in scalar performance.*

This imbalance was a problem on many early vector processors, and a place where Seymour Cray (the architect of the Cray computers) rewrote the rules. Many of the early vector processors had comparatively slow scalar units (as well as large start-up overheads). Even today, a processor with lower vector performance but better scalar performance can outperform a processor with higher peak vector performance. Good scalar performance keeps down overhead costs (strip mining, for example) and reduces the impact of Amdahl’s law.

An excellent example of this comes from comparing a fast scalar processor and a vector processor with lower scalar performance. The Livermore Fortran kernels are a collection of 24 scientific kernels with varying degrees of vectorization. Figure 4.34 shows the performance of two different processors on this benchmark. Despite the vector processor’s higher peak performance, its low scalar performance makes it slower than a fast scalar processor as measured by the harmonic mean.

The flip of this danger today is increasing vector performance—say, by increasing the number of lanes—without increasing scalar performance. Such myopia is another path to an unbalanced computer.

The next fallacy is closely related.

Fallacy *You can get good vector performance without providing memory bandwidth.*

As we saw with the DAXPY loop and the Roofline model, memory bandwidth is quite important to all SIMD architectures. DAXPY requires 1.5 memory references per floating-point operation, and this ratio is typical of many scientific codes. Even if the floating-point operations took no time, a Cray-1 could not increase the performance of the vector sequence used, because it is memory-limited. The Cray-1 performance on Linpack jumped when the compiler used blocking to change the computation so that values could be kept in the vector registers. This approach lowered the number of memory references per FLOP and improved the performance by nearly a factor of two! Thus the memory bandwidth on the Cray-1 became sufficient for a loop that formerly required more bandwidth.

Processor	Minimum rate for any loop (MFLOPS)	Maximum rate for any loop (MFLOPS)	Harmonic mean of all 24 loops (MFLOPS)
MIPS M/120-5	0.80	3.89	1.85
Stardent-1500	0.41	10.08	1.72

Figure 4.34 Performance measurements for the Livermore Fortran kernels on two different processors. Both the MIPS M/120-5 and the Stardent-1500 (formerly the Ardent Titan-1) use a 16.7 MHz MIPS R2000 chip for the main CPU. The Stardent-1500 uses its vector unit for scalar FP and has about half the scalar performance (as measured by the minimum rate) of the MIPS M/120-5, which uses the MIPS R2010 FP chip. The vector processor is more than a factor of $2.5\times$ faster for a highly vectorizable loop (maximum rate). However, the lower scalar performance of the Stardent-1500 negates the higher vector performance when total performance is measured by the harmonic mean on all 24 loops.

Fallacy *On GPUs, just add more threads if you don't have enough memory performance.*

GPUs use many CUDA Threads to hide the latency to main memory. If memory accesses are scattered or not correlated among CUDA Threads, the memory system will get progressively slower in responding to each individual request. Eventually, even many threads will not cover the latency. For the “more CUDA Threads” strategy to work, not only do you need lots of CUDA Threads, but the CUDA Threads themselves also must be well behaved in terms of locality of memory accesses.

4.9

Concluding Remarks

Data-level parallelism is increasing in importance for personal mobile devices, given the popularity of applications showing the importance of audio, video, and games on these devices. When combined with a model that is easier to program than task-level parallelism and with potentially better energy efficiency, it's easy to see why there has been a renaissance for data-level parallelism in this decade.

We are seeing system processors take on more of the characteristics of GPUs, and vice versa. One of the biggest differences in performance between conventional processors and GPUs has been for gather-scatter addressing. Traditional vector architectures show how to add such addressing to SIMD instructions, and we expect to see more ideas added from the well-proven vector architectures to SIMD extensions over time.

As we said in the opening of [Section 4.4](#), the GPU question is not simply which architecture is best, but given the hardware investment to do graphics well, how can it be enhanced to support computation that is more general? Although vector architectures have many advantages on paper, it remains to be proven whether vector architectures can be as good a foundation for graphics as GPUs. RISC-V has embraced vector over SIMD. Thus, like architecture debates of the past, the marketplace will help determine the importance of the strengths and weaknesses of two styles of data parallel architectures.

4.10

Historical Perspective and References

Section M.6 (available online) features a discussion on the Illiac IV (a representative of the early SIMD architectures) and the Cray-1 (a representative of vector architectures). We also look at multimedia SIMD extensions and the history of GPUs.

Case Study and Exercises by Jason D. Bakos

Case Study: Implementing a Vector Kernel on a Vector Processor and GPU

Concepts illustrated by this case study

- Programming Vector Processors
- Programming GPUs
- Performance Estimation

MrBayes is a popular computational biology application for inferring the evolutionary histories among a set of input species based on their prealigned DNA sequence data of length n . MrBayes works by performing an heuristic search over the space of all binary tree topologies for which the inputs are the leaves. In order to evaluate a particular tree, the application must compute an $n \times 4$ conditional likelihood table (named `c1P`) for each interior node. The table is a function of the conditional likelihood tables of the node's two descendent nodes (`c1L` and `c1R`, single precision floating point) and the 4×4 transition probability table (`tiPL` and `tiPR`, single precision floating point). One of this application's kernels is the computation of this conditional likelihood table and is shown as follows:

```
for (k=0; k<seq_length; k++) {
    c1P[h++] = (tiPL[AA]*c1L[A] + tiPL[AC]*c1L[C] +
               tiPL[AG]*c1L[G] + tiPL[AT]*c1L[T])*
               (tiPR[AA]*c1R[A] + tiPR[AC]*c1R[C] +
               tiPR[AG]*c1R[G] + tiPR[AT]*c1R[T]);
    c1P[h++] = (tiPL[CA]*c1L[A] + tiPL[CC]*c1L[C] +
               tiPL[CG]*c1L[G] + tiPL[CT]*c1L[T])*
               (tiPR[CA]*c1R[A] + tiPR[CC]*c1R[C] +
               tiPR[CG]*c1R[G] + tiPR[CT]*c1R[T]);
    c1P[h++] = (tiPL[GA]*c1L[A] + tiPL[GC]*c1L[C] +
               tiPL[GG]*c1L[G] + tiPL[GT]*c1L[T])*
               (tiPR[GA]*c1R[A] + tiPR[GC]*c1R[C] +
               tiPR[GG]*c1R[G] + tiPR[GT]*c1R[T]);
    c1P[h++] = (tiPL[TA]*c1L[A] + tiPL[TC]*c1L[C] +
               tiPL[TG]*c1L[G] + tiPL[TT]*c1L[T])*
               (tiPR[TA]*c1R[A] + tiPR[TC]*c1R[C] +
               tiPR[TG]*c1R[G] + tiPR[TT]*c1R[T]);
    c1L += 4;
    c1R += 4;
}
```

4.1 [25] <4.1, 4.2> Assume the constants shown as follows.

Constants	Values
AA,AC,AG,AT	0,1,2,3
CA,CC,CG,CT	4,5,6,7
GA,GC,GG,GT	8,9,10,11
TA,TC,TG,TT	12,13,14,15
A,C,G,T	0,1,2,3

Write code for RISC-V and RV64V. Assume the starting addresses of `tiPL`, `tiPR`, `clL`, `clR`, and `clP` are in `RtiPL`, `RtiPR`, `RclL`, `RclR`, and `RclP`, respectively. Do not unroll the loop. To facilitate vector addition reductions, assume that we add the following instructions to RV64V:

Vector Summation Reduction Single Precision:

```
vsum Fd, Vs
```

This instruction performs a summation reduction on a vector register `Vs`, writing to the sum into scalar register `Fd`.

- 4.2 [5] <4.1, 4.2> Assuming `seq_length == 500`, what is the dynamic instruction count for both implementations?
- 4.3 [25] <4.1, 4.2> Assume that the vector reduction instruction is executed on the vector functional unit, similar to a vector add instruction. Show how the code sequence lays out in convoys assuming a single instance of each vector functional unit. How many chimes will the code require? How many cycles per FLOP are needed, ignoring vector instruction issue overhead?
- 4.4 [15] <4.1, 4.2> Consider the possibility of unrolling the loop and mapping multiple iterations to vector operations. Assume that you can use scatter-gather loads and stores (`vldi` and `vsti`). How does this affect the way you can write the RV64V code for this kernel?
- 4.5 [25] <4.4> Now assume we want to implement the MrBayes kernel on a GPU using a single thread block. Rewrite the C code of the kernel using CUDA. Assume that pointers to the conditional likelihood and transition probability tables are specified as parameters to the kernel. Invoke one thread for each iteration of the loop. Load any reused values into shared memory before performing operations on it.
- 4.6 [15] <4.4> With CUDA we can use coarse-grain parallelism at the block level to compute the conditional likelihood of multiple nodes in parallel. Assume that we want to compute the conditional likelihood from the bottom of the tree up. Assume `seq_length == 500` for all nodes and that the group of tables for each of the 12 leaf nodes is stored in consecutive memory locations in the order of node number (e.g., the m th element of `clP` on node n is at `clP[n*4*seq_length+m*4]`). Assume that we want to compute the conditional likelihood for nodes 12–17, as shown in [Figure 4.35](#). Change the method by which you compute the array indices in your answer from Exercise 4.5 to include the block number.
- 4.7 [15] <4.4> Convert your code from Exercise 4.6 into PTX code. How many instructions are needed for the kernel?
- 4.8 [10] <4.4> How well do you expect this code to perform on a GPU? Explain your answer.

Figure 4.35 Sample tree.

Exercises

- 4.9 [10/20/20/15/15] <4.2> Consider the following code, which multiplies two vectors that contain single-precision complex values:

```

for (i=0; i < 300; i++) {
    c_re[i] = a_re[i] * b_re[i] - a_im[i] * b_im[i];
    c_im[i] = a_re[i] * b_im[i] + a_im[i] * b_re[i];
}

```

Assume that the processor runs at 700 MHz and has a maximum vector length of 64. The load/store unit has a start-up overhead of 15 cycles; the multiply unit, 8 cycles; and the add/subtract unit, 5 cycles.

- [10] <4.3> What is the arithmetic intensity of this kernel? Justify your answer.
- [20] <4.2> Convert this loop into RV64V assembly code using strip mining.
- [20] <4.2> Assuming chaining and a single memory pipeline, how many chimes are required? How many clock cycles are required per complex result value, including start-up overhead?
- [15] <4.2> If the vector sequence is chained, how many clock cycles are required per complex result value, including overhead?
- [15] <4.2> Now assume that the processor has three memory pipelines and chaining. If there are no bank conflicts in the loop's accesses, how many clock cycles are required per result?

- 4.10 [30] <4.2,4.3,4.4> In this problem, we will compare the performance of a vector processor with a hybrid system that contains a scalar processor and a GPU-based coprocessor. In the hybrid system, the host processor has superior scalar performance to the GPU, so in this case all scalar code is executed on the host processor while all vector code is executed on the GPU. We will refer to the first system as the vector computer and the second system as the hybrid computer. Assume that your target application contains a vector kernel with an arithmetic intensity of 0.5 FLOPs per DRAM byte accessed; however, the application also has a scalar component that must be performed before and after the kernel in order to prepare the input vectors and output vectors, respectively. For a sample dataset, the scalar portion of the code requires 400 ms of execution time on both the vector processor and the host processor in the hybrid system. The kernel reads input vectors consisting of 200 MB of data and has output data consisting of 100 MB of data. The vector processor has a peak memory bandwidth of 30 GB/s and the GPU has a peak memory bandwidth of 150 GB/s. The hybrid system has an additional overhead that requires all input vectors to be transferred between the host memory and GPU local memory before and after the kernel is invoked. The hybrid system has a direct memory access (DMA) bandwidth of 10 GB/s and an average latency of 10 ms. Assume that both the vector processor and GPU are performance bound by memory bandwidth. Compute the execution time required by both computers for this application.
- 4.11 [15/25/25] <4.4, 4.5> [Section 4.5](#) discussed the reduction operation that reduces a vector down to a scalar by repeated application of an operation. A reduction is a special type of a loop recurrence. An example is shown as follows:

```
dot=0.0;
for (i=0;i <64;i++) dot = dot + a[i] * b[i];
```

A vectorizing compiler might apply a transformation called *scalar expansion*, which expands dot into a vector and splits the loop such that the multiply can be performed with a vector operation, leaving the reduction as a separate scalar operation:

```
for (i=0;i <64;i++) dot[i] = a[i] * b[i];
for (i=1;i <64;i++) dot[0] = dot[0] + dot[i];
```

As mentioned in [Section 4.5](#), if we allow the floating-point addition to be associative, there are several techniques available for parallelizing the reduction.

- a. [15] <4.4, 4.5> One technique is called recurrence doubling, which adds sequences of progressively shorter vectors (ie, two 32-element vectors, then two 16-element vectors, and so on). Show how the C code would look for executing the second loop in this way.
- b. [25] <4.4, 4.5> In some vector processors, the individual elements within the vector registers are addressable. In this case, the operands to a vector operation may be two different parts of the same vector register. This allows another solution for the reduction called *partial sums*. The idea is to reduce the vector to m sums where m is

the total latency through the vector functional unit, including the operand read and write times. Assume that the VMIPS vector registers are addressable (e.g., you can initiate a vector operation with the operand `V1(16)`, indicating that the input operand begins with element 16). Also, assume that the total latency for adds, including the operand read and result write, is eight cycles. Write a VMIPS code sequence that reduces the contents of `V1` to eight partial sums.

- c. [25] <4.4, 4.5> When performing a reduction on a GPU, one thread is associated with each element in the input vector. The first step is for each thread to write its corresponding value into shared memory. Next, each thread enters a loop that adds each pair of input values. This reduces the number of elements by half after each iteration, meaning that the number of active threads also reduces by half after each iteration. In order to maximize the performance of the reduction, the number of fully populated warps should be maximized throughout the course of the loop. In other words, the active threads should be contiguous. Also, each thread should index the shared array in such a way as to avoid bank conflicts in the shared memory. The following loop violates only the first of these guidelines and also uses the modulo operator, which is very expensive for GPUs:

```
unsigned int tid = threadIdx.x;
for(unsigned int s=1; s < blockDim.x; s *= 2) {
    if((tid % (2*s)) == 0) {
        sdata[tid] += sdata[tid + s];
    }
    __syncthreads();
}
```

Rewrite the loop to meet these guidelines and eliminate the use of the modulo operator. Assume that there are 32 threads per warp and a bank conflict occurs whenever two or more threads from the same warp reference an index whose modulo by 32 are equal.

- 4.12 [10/10/10/10] <4.3> The following kernel performs a portion of the finite-difference time-domain (FDTD) method for computing Maxwell's equations in a three-dimensional space, part of one of the SPEC06fp benchmarks:

```
for (int x=0; x < NX -1; x++) {
    for (int y=0; y < NY -1; y++) {
        for (int z=0; z < NZ -1; z++) {
            int index = x*NY*NZ + y*NZ + z;
            if (y > 0 && x > 0) {
                material = IDx[index];
                dH1 = (Hz[index] - Hz[index-incrementY])/dy[y];
                dH2 = (Hy[index] - Hy[index-incrementZ])/dz[z];
                Ex[index] = Ca[material]*Ex[index] + Cb[material]*
                    (dH2 - dH1);
            }
        }
    }
}
```

Assume that `dH1`, `dH2`, `Hy`, `Hx`, `dy`, `dz`, `Ca`, `Cb`, and `Ex` are all single-precision floating-point arrays. Assume `IDx` is an array of unsigned int.

- a. [10] <4.3> What is the arithmetic intensity of this kernel?
 - b. [10] <4.3> Is this kernel amenable to vector or SIMD execution? Why or why not?
 - c. [10] <4.3> Assume this kernel is to be executed on a processor that has 30 GB/s of memory bandwidth. Will this kernel be memory bound or compute bound?
 - d. [10] <4.3> Develop a roofline model for this processor, assuming it has a peak computational throughput of 85 GFLOP/s.
- 4.13 [10/15] <4.4> Assume a GPU architecture that contains 10 SIMD processors. Each SIMD instruction has a width of 32 and each SIMD processor contains 8 lanes for single-precision arithmetic and load/store instructions, meaning that each nondiverged SIMD instruction can produce 32 results every 4 cycles. Assume a kernel that has divergent branches that causes, on average, 80% of threads to be active. Assume that 70% of all SIMD instructions executed are single-precision arithmetic and 20% are load/store. Because not all memory latencies are covered, assume an average SIMD instruction issue rate of 0.85. Assume that the GPU has a clock speed of 1.5 GHz.
- a. [10] <4.4> Compute the throughput, in GFLOP/s, for this kernel on this GPU.
 - b. [15] <4.4> Assume that you have the following choices:
 - (1) Increasing the number of single-precision lanes to 16
 - (2) Increasing the number of SIMD processors to 15 (assume this change doesn't affect any other performance metrics and that the code scales to the additional processors)
 - (3) Adding a cache that will effectively reduce memory latency by 40%, which will increase instruction issue rate to 0.95
 What is speedup in throughput for each of these improvements?
- 4.14 [10/15/15] <4.5> In this exercise, we will examine several loops and analyze their potential for parallelization.

- a. [10] <4.5> Does the following loop have a loop-carried dependency?

```
for (i=0; i < 100; i++) {
    A[i] = B[2*i+4];
    B[4*i+5] = A[i];
}
```

- b. [15] <4.5> In the following loop, find all the true dependences, output dependences, and antidependences. Eliminate the output dependences and antidependences by renaming.

```
for (i=0; i < 100; i++) {
    A[i] = A[i] * B[i]; /* S1 */
}
```

```

B[i] = A[i] + c; /* S2 */
A[i] = C[i] * c; /* S3 */
C[i] = D[i] * A[i]; /* S4 */

```

c. [15] <4.5> Consider the following loop:

```

for (i=0; i < 100; i++) {
    A[i] = A[i] + B[i]; /* S1 */
    B[i+1] = C[i] + D[i]; /* S2 */
}

```

Are there dependences between S1 and S2? Is this loop parallel? If not, show how to make it parallel.

4.15 [10] <4.4> List and describe at least four factors that influence the performance of GPU kernels. In other words, which runtime behaviors that are caused by the kernel code cause a reduction in resource utilization during kernel execution?

4.16 [10] <4.4> Assume a hypothetical GPU with the following characteristics:

- Clock rate 1.5 GHz
- Contains 16 SIMD processors, each containing 16 single-precision floating-point units
- Has 100 GB/s off-chip memory bandwidth

Without considering memory bandwidth, what is the peak single-precision floating-point throughput for this GPU in GFLOP/s, assuming that all memory latencies can be hidden? Is this throughput sustainable given the memory bandwidth limitation?

4.17 [60] <4.4> For this programming exercise, you will write and characterize the behavior of a CUDA kernel that contains a high amount of data-level parallelism but also contains conditional execution behavior. Use the NVIDIA CUDA Toolkit along with GPU-SIM from the University of British Columbia (<http://www.gpgpu-sim.org/>) or the CUDA Profiler to write and compile a CUDA kernel that performs 100 iterations of Conway's Game of Life for a 256×256 game board and returns the final state of the game board to the host. Assume that the board is initialized by the host. Associate one thread with each cell. Make sure you add a barrier after each game iteration. Use the following game rules:

- Any live cell with fewer than two live neighbors dies.
- Any live cell with two or three live neighbors lives on to the next generation.
- Any live cell with more than three live neighbors dies.
- Any dead cell with exactly three live neighbors becomes a live cell.

After finishing the kernel answer the following questions:

a. [60] <4.4> Compile your code using the `-ptx` option and inspect the PTX representation of your kernel. How many PTX instructions make up the PTX

implementation of your kernel? Did the conditional sections of your kernel include branch instructions or only predicated nonbranch instructions?

- b. [60] <4.4> After executing your code in the simulator, what is the dynamic instruction count? What is the achieved instructions per cycle (IPC) or instruction issue rate? What is the dynamic instruction breakdown in terms of control instructions, arithmetic-logical unit (ALU) instructions, and memory instructions? Are there any shared memory bank conflicts? What is the effective off-chip memory bandwidth?
- c. [60] <4.4> Implement an improved version of your kernel where off-chip memory references are coalesced and observe the differences in runtime performance.

Thread-Level Parallelism

The turning away from the conventional organization came in the middle 1960s, when the law of diminishing returns began to take effect in the effort to increase the operational speed of a computer. . . . Electronic circuits are ultimately limited in their speed of operation by the speed of light . . . and many of the circuits were already operating in the nanosecond range.

W. Jack Bouknight et al.,
The Illiac IV System (1972)

We are dedicating all of our future product development to multicore designs. We believe this is a key inflection point for the industry.

Intel President Paul Otellini,
*describing Intel's future direction at the
Intel Developer Forum in 2005*

Since 2004 processor designers have increased core counts to exploit Moore's Law scaling, rather than focusing on single-core performance. The failure of Dennard scaling, to which the shift to multicore parts is partially a response, may soon limit multicore scaling just as single-core scaling has been curtailed.

*Power Limitations and Dark Silicon
Challenge the Future of Multicore* (2012)

5.1

Introduction

As the quotations that open this chapter show, the view that advances in uniprocessor architecture were nearing an end has been held by some researchers for many years. Clearly, these views were premature; in fact, during the period of 1986–2003, uniprocessor performance growth, driven by the microprocessor, was at its highest rate since the first transistorized computers in the late 1950s and early 1960s.

Nonetheless, the importance of multiprocessors was growing throughout the 1990s as designers sought a way to build servers and supercomputers that achieved higher performance than a single microprocessor, while exploiting the tremendous cost-performance advantages of commodity microprocessors. As we discussed in Chapters 1 and 3, the slowdown in uniprocessor performance arising from diminishing returns in exploiting instruction-level parallelism (ILP) combined with growing concern over power has led to a new era in computer architecture—an era where multiprocessors play a major role from the low end to the high end. The second quotation captures this clear inflection point.

This increased importance of multiprocessing reflects several major factors:

- The dramatically lower efficiencies in silicon and energy use that were encountered between 2000 and 2005 as designers attempted to find and exploit more ILP, which turned out to be inefficient, since power and silicon costs grew faster than performance. Other than ILP, the only scalable and general-purpose way we know to increase performance faster than the basic technology allows (from a switching perspective) is through multiprocessing.
- A growing interest in high-end servers as cloud computing and software-as-a-service become more important.
- A growth in data-intensive applications driven by the availability of massive amounts of data on the Internet.
- The insight that increasing performance on the desktop is less important (outside of graphics, at least), either because current performance is acceptable or because highly compute- and data-intensive applications are being done on the cloud.
- An improved understanding of how to use multiprocessors effectively, especially in server environments where there is significant inherent parallelism, arising from large datasets (usually in the form of data parallelism), “natural-world” parallelism (which occurs in scientific and engineering codes), or parallelism among large numbers of independent requests (request-level parallelism).
- The advantages of leveraging a design investment by replication rather than unique design; all multiprocessor designs provide such leverage.

The third quotation reminds us that multicore may provide only limited possibilities for scaling performance. The combination of Amdahl’s Law effects and the

end of Dennard scaling mean that the future of multicore may be limited, at least as a method of scaling up the performance of single applications. We return to this topic late in the chapter.

In this chapter, we focus on exploiting thread-level parallelism (TLP). TLP implies the existence of multiple program counters and thus is exploited primarily through MIMDs. Although MIMDs have been around for decades, the movement of thread-level parallelism to the forefront across the range of computing from embedded applications to high-end servers is relatively recent. Likewise, the extensive use of thread-level parallelism for a wide-range of general-purpose applications, versus either transaction processing or scientific applications, is relatively new.

Our focus in this chapter is on *multiprocessors*, which we define as computers consisting of tightly coupled processors whose coordination and usage are typically controlled by a single operating system and that share memory through a shared address space. Such systems exploit thread-level parallelism through two different software models. The first is the execution of a tightly coupled set of threads collaborating on a single task, which is typically called *parallel processing*. The second is the execution of multiple, relatively independent processes that may originate from one or more users, which is a form of *request-level parallelism*, although at a much smaller scale than what we explore in the next chapter. Request-level parallelism may be exploited by a single application running on multiple processors, such as a database responding to queries, or multiple applications running independently, often called *multiprogramming*.

The multiprocessors we examine in this chapter typically range in size from a dual processor to dozens and sometimes hundreds of processors and communicate and coordinate through the sharing of memory. Although sharing through memory implies a shared address space, it does not necessarily mean there is a single physical memory. Such multiprocessors include both single-chip systems with multiple cores, known as *multicore*, and computers consisting of multiple chips, each of which is typically a multicore. Many companies make such multiprocessors, including HP, Dell, Cisco, IBM, SGI, Lenovo, Oracle, Fujitsu, and many others.

In addition to true multiprocessors, we will return to the topic of multithreading, a technique that supports multiple threads executing in an interleaved fashion on a single multiple-issue processor. Many multicore processors also include support for multithreading.

In the next chapter, we consider ultrascale computers built from very large numbers of processors, connected with networking technology (not necessarily the same networking technology used to connect computers to the Internet) and often called *clusters*; these large-scale systems are used for cloud computing primarily with massive numbers of independent tasks being executed in parallel. More recently, computationally intensive tasks that can be easily made parallel, such as Search and certain machine learning algorithms have also made use of clusters. When these clusters grow to tens of thousands of servers and beyond, we call them *warehouse-scale computers*. Amazon, Google, Microsoft, and Facebook all make warehouse-scale computers.

In addition to the multiprocessors we study here and the warehouse-scaled systems of the next chapter, there are a range of special large-scale multiprocessor systems, sometimes called *multicomputers*, which are less tightly coupled than the multiprocessors examined in this chapter but usually more tightly coupled than the warehouse-scale systems of the next chapter. The primary use for such multicomputers is in high-end scientific computation, although they are sometimes used for commercial applications filling the niche between multiprocessors and warehouse-scale computers. The Cray X series and IBM BlueGene are typical examples of these multicomputers.

Many other books, such as Culler et al. (1999), cover such systems in detail. Because of the large and changing nature of the field of multiprocessing (the just-mentioned Culler et al. reference is over 1000 pages and discusses only multiprocessing!), we have chosen to focus our attention on what we believe is the most important and general-purpose portions of the computing space. Appendix I discusses some of the issues that arise in building such computers in the context of large-scale scientific applications.

Our focus will be on multiprocessors with roughly 4–256 processor cores, which might occupy anywhere from 4 to 16 separate chips. Such designs vastly dominate in terms of both units and dollars. In large-scale multiprocessors, the interconnection networks are a critical part of the design; Appendix F focuses on that topic.

Multiprocessor Architecture: Issues and Approach

To take advantage of an MIMD multiprocessor with n processors, we must usually have at least n threads or processes to execute; with multithreading, which is present in most multicore chips today, that number is 2–4 times higher. The independent threads within a single process are typically identified by the programmer or created by the operating system (from multiple independent requests). At the other extreme, a thread may consist of a few tens of iterations of a loop, generated by a parallel compiler exploiting data parallelism in the loop. Although the amount of computation assigned to a thread, called the *grain size*, is important in considering how to exploit thread-level parallelism efficiently, the important qualitative distinction from instruction-level parallelism is that thread-level parallelism is identified at a high level by the software system or programmer and that the threads consist of hundreds to millions of instructions that may be executed in parallel.

Threads can also be used to exploit data-level parallelism, although the overhead is usually higher than would be seen with an SIMD processor or with a GPU (see Chapter 4). This overhead means that grain size must be sufficiently large to exploit the parallelism efficiently. For example, although a vector processor or GPU may be able to efficiently parallelize operations on short vectors, the resulting grain size when the parallelism is split among many threads may be so small that the overhead makes the exploitation of the parallelism prohibitively expensive in an MIMD.

Existing shared-memory multiprocessors fall into two classes, depending on the number of processors involved, which in turn dictates a memory organization and interconnect strategy. We refer to the multiprocessors by their memory organization because what constitutes a small or large number of processors continues to change over time.

The first group, which we call *symmetric (shared-memory) multiprocessors* (SMPs), or *centralized shared-memory multiprocessors*, features small to moderate numbers of cores, typically 32 or fewer. For multiprocessors with such small processor counts, it is possible for the processors to share a single centralized memory that all processors have equal access to, thus the term *symmetric*. In multicore chips, the memory is often shared in a centralized fashion among the cores; most existing multicores are SMPs, but not all. (Note that some literature mistakenly appears to use SMP to stand for Shared Memory Processor, but this usage is erroneous.)

Some multicores have nonuniform access to the outermost cache, a structure called *NUCA* for *Nonuniform Cache Access*, and are thus not truly SMPs, even if they have a single main memory. The IBM Power8 has distributed L3 caches with nonuniform access time to different addresses in L3.

In multiprocessors consisting of multiple multicore chips, there are often separate memories for each multicore chip. Thus the memory is distributed rather than centralized. As we will see later in the chapter, many designs with distributed memory have fast access to a local memory and much slower access to remote memory; often the differences in access time to various remote memories are small in comparison to the difference between the access times to the local memory and to a remote memory. In such designs, the programmer and software system need to be aware of whether accesses are to local or remote memory, but may be able to ignore the distribution of accesses among remote memories. Because an SMP approach becomes less attractive with a growing number of processors, most of the very largest multiprocessors use some form of distributed memory.

SMP architectures are also sometimes called *uniform memory access* (UMA) multiprocessors, arising from the fact that all processors have a uniform latency from memory, even if the memory is organized into multiple banks. [Figure 5.1](#) shows what these multiprocessors look like. The architecture of SMPs is the topic of [Section 5.2](#), and we explain the approach in the context of a multicore.

The alternative design approach consists of multiprocessors with physically distributed memory, called *distributed shared memory* (DSM). [Figure 5.2](#) shows what these multiprocessors look like. To support larger processor counts, memory must be distributed among the processors rather than centralized; otherwise, the memory system would not be able to support the bandwidth demands of a larger number of processors without incurring excessively long access latency.

With the rapid increase in processor performance and the associated increase in a processor's memory bandwidth requirements, the size of a multiprocessor for

Figure 5.1 Basic structure of a centralized shared-memory multiprocessor based on a multicore chip. Multiple processor-cache subsystems share the same physical memory, typically with one level of shared cache on the multicore, and one or more levels of private per-core cache. The key architectural property is the uniform access time to all of the memory from all of the processors. In a multichip design, an interconnection network links the processors and the memory, which may be one or more banks. In a single-chip multicore, the interconnection network is simply the memory bus.

which distributed memory is preferred continues to shrink. The introduction of multicore processors has meant that even some 2-chip multiprocessors, which might have 16–64 processor cores, use distributed memory. The larger number of processors also raises the need for a high-bandwidth interconnect, of which we will see examples in Appendix F. Both directed networks (i.e., switches) and indirect networks (typically multidimensional meshes) are used.

Distributing the memory among the nodes both increases the bandwidth and reduces the latency to local memory. A DSM multiprocessor is also called a *NUMA* (nonuniform memory access) because the access time depends on the location of a data word in memory. The key disadvantages for a DSM are that communicating data among processors becomes somewhat more complex and a DSM requires more effort in the software to take advantage of the increased memory bandwidth

Figure 5.2 The basic architecture of a distributed-memory multiprocessor in 2017 typically consists of a multicore multiprocessor chip with memory and possibly I/O attached and an interface to an interconnection network that connects all the nodes. Each processor core shares the entire memory, although the access time to the local memory attached to the core's chip will be much faster than the access time to remote memories.

afforded by distributed memories. Because most multicore-based multiprocessors with more than a few processor chips use distributed memory, we will explain the operation of distributed memory multiprocessors from this viewpoint.

In both SMP and DSM architectures, communication among threads occurs through a shared address space, meaning that a memory reference can be made by any processor to any memory location, assuming it has the correct access rights. The term *shared memory* associated with both SMP and DSM refers to the fact that the *address space* is shared.

In contrast, the clusters and warehouse-scale computers in the next chapter look like individual computers connected by a network, and the memory of one processor cannot be accessed by another processor without the assistance of software protocols running on both processors. In such designs, message-passing protocols are used to communicate data among processors.

Challenges of Parallel Processing

The application of multiprocessors ranges from running independent tasks with essentially no communication to running parallel programs where threads must communicate to complete the task. Two important hurdles, both explainable with Amdahl's Law, make parallel processing challenging. To overcome these hurdles typically requires a comprehensive approach that addresses the choice of

algorithm and its implementation, the underlying programming language and system, the operating system and its support functions, and the architecture and hardware implementation. Although in many instances, one of these is a key bottleneck, when scaling to a larger processor counts (approaching 100 or more), often *all* aspects of the software and hardware need attention.

The first hurdle has to do with the limited parallelism available in programs, and the second arises from the relatively high cost of communications. Limitations in available parallelism make it difficult to achieve good speedups in any parallel processor, as our first example shows.

Example Suppose you want to achieve a speedup of 80 with 100 processors. What fraction of the original computation can be sequential?

Answer Recall from [Chapter 1](#) that Amdahl's Law is

$$\text{Speedup} = \frac{1}{\frac{\text{Fraction}_{\text{enhanced}}}{\text{Speedup}_{\text{enhanced}}} + (1 - \text{Fraction}_{\text{enhanced}})}$$

For simplicity in this example, assume that the program operates in only two modes: parallel with all processors fully used, which is the enhanced mode, or serial with only one processor in use. With this simplification, the speedup in enhanced mode is simply the number of processors, whereas the fraction of enhanced mode is the time spent in parallel mode. Substituting into the previous equation:

$$80 = \frac{1}{\frac{\text{Fraction}_{\text{parallel}}}{100} + (1 - \text{Fraction}_{\text{parallel}})}$$

Simplifying this equation yields:

$$\begin{aligned} 0.8 \times \text{Fraction}_{\text{parallel}} + 80 \times (1 - \text{Fraction}_{\text{parallel}}) &= 1 \\ 80 - 79.2 \times \text{Fraction}_{\text{parallel}} &= 1 \\ \text{Fraction}_{\text{parallel}} &= \frac{80 - 1}{79.2} \\ \text{Fraction}_{\text{parallel}} &= 0.9975 \end{aligned}$$

Thus, to achieve a speedup of 80 with 100 processors, only 0.25% of the original computation can be sequential! Of course, to achieve linear speedup (speedup of n with n processors), the entire program must usually be parallel with no serial portions. In practice, programs do not just operate in fully parallel or sequential mode, but often use less than the full complement of the processors when running in parallel mode. Amdahl's Law can be used to analyze applications with varying amounts of speedup, as the next example shows.

Example Suppose we have an application running on a 100-processor multiprocessor, and assume that application can use 1, 50, or 100 processors. If we assume that 95% of the time we can use all 100 processors, how much of the remaining 5% of the execution time must employ 50 processors if we want a speedup of 80?

Answer We use Amdahl's Law with more terms:

$$\text{Speedup} = \frac{1}{\frac{\text{Fraction}_{100}}{\text{Speedup}_{100}} + \frac{\text{Fraction}_{50}}{\text{Speedup}_{50}} + (1 - \text{Fraction}_{100} - \text{Fraction}_{50})}$$

Substituting in:

$$80 = \frac{1}{\frac{0.95}{100} + \frac{\text{Fraction}_{50}}{50} + (1 - 0.95 - \text{Fraction}_{80})}$$

Simplifying:

$$\begin{aligned} 0.76 + 1.6 \times \text{Fraction}_{50} + 4.0 - 80 \times \text{Fraction}_{50} &= 1 \\ 4.76 - 78.4 \times \text{Fraction}_{50} &= 1 \\ \text{Fraction}_{50} &= 0.048 \end{aligned}$$

If 95% of an application can use 100 processors perfectly, to get a speedup of 80, 4.8% of the remaining time must be spent using 50 processors and only 0.2% can be serial!

The second major challenge in parallel processing involves the large latency of remote access in a parallel processor. In existing shared-memory multiprocessors, communication of data between separate cores may cost 35–50 clock cycles and among cores on separate chips anywhere from 100 clock cycles to as much as 300 or more clock cycles (for large-scale multiprocessors), depending on the communication mechanism, the type of interconnection network, and the scale of the multiprocessor. The effect of long communication delays is clearly substantial. Let's consider a simple example.

Example Suppose we have an application running on a 32-processor multiprocessor that has a 100 ns delay to handle a reference to a remote memory. For this application, assume that all the references except those involving communication hit in the local memory hierarchy, which is obviously optimistic. Processors are stalled on a remote request, and the processor clock rate is 4 GHz. If the base CPI (assuming that all references hit in the cache) is 0.5, how much faster is the multiprocessor if there is no communication versus if 0.2% of the instructions involve a remote communication reference?

Answer It is simpler to first calculate the clock cycles per instruction. The effective CPI for the multiprocessor with 0.2% remote references is

$$\begin{aligned}\text{CPI} &= \text{Base CPI} + \text{Remote request rate} \times \text{Remote request cost} \\ &= 0.5 + 0.2\% \times \text{Remote request cost}\end{aligned}$$

The remote request cost is

$$\frac{\text{Remote access cost}}{\text{Cycle time}} = \frac{100\text{ns}}{0.25\text{ns}} = 400 \text{ cycles}$$

Therefore we can compute the CPI:

$$\begin{aligned}\text{CPI} &= 0.5 + 0.20\% \times 400 \\ &= 1.3\end{aligned}$$

The multiprocessor with all local references is $1.3/0.5 = 2.6$ times faster. In practice, the performance analysis is much more complex because some fraction of the noncommunication references will miss in the local hierarchy and the remote access time does not have a single constant value. For example, the cost of a remote reference could be worse because contention caused by many references trying to use the global interconnect can lead to increased delays, or the access time might be better if memory were distributed and the access was to the local memory.

This problem could have also been analyzed using Amdahl's Law, an exercise we leave to the reader.

These problems—insufficient parallelism and long-latency remote communication—are the two biggest performance challenges in using multiprocessors. The problem of inadequate application parallelism must be attacked primarily in software with new algorithms that offer better parallel performance, as well as by software systems that maximize the amount of time spent executing with the full complement of processors. Reducing the impact of long remote latency can be attacked both by the architecture and by the programmer. For example, we can reduce the frequency of remote accesses with either hardware mechanisms, such as caching shared data, or software mechanisms, such as restructuring the data to make more accesses local. We can try to tolerate the latency by using multithreading (discussed later in this chapter) or by using prefetching (a topic we cover extensively in [Chapter 2](#)).

Much of this chapter focuses on techniques for reducing the impact of long remote communication latency. For example, [Sections 5.2 through 5.4](#) discuss how caching can be used to reduce remote access frequency, while maintaining a coherent view of memory. [Section 5.5](#) discusses synchronization, which, because it inherently involves interprocessor communication and also can limit parallelism, is a major potential bottleneck. [Section 5.6](#) covers latency-hiding techniques and memory consistency models for shared memory. In Appendix I, we focus primarily on larger-scale multiprocessors that are used predominantly for scientific work.

In that appendix, we examine the nature of such applications and the challenges of achieving speedup with dozens to hundreds of processors.

5.2

Centralized Shared-Memory Architectures

The observation that the use of large, multilevel caches can substantially reduce the memory bandwidth demands of a processor is the key insight that motivates centralized memory multiprocessors. Originally, these processors were all single-core and often took an entire board, and memory was located on a shared bus. With more recent, higher-performance processors, the memory demands have outstripped the capability of reasonable buses, and recent microprocessors directly connect memory to a single chip, which is sometimes called a *backside* or *memory bus* to distinguish it from the bus used to connect to I/O. Accessing a chip's local memory whether for an I/O operation or for an access from another chip requires going through the chip that "owns" that memory. Thus access to memory is asymmetric: faster to the local memory and slower to the remote memory. In a multicore that memory is shared among all the cores on a single chip, but the asymmetric access to the memory of one multicore from the memory of another usually remains.

Symmetric shared-memory machines usually support the caching of both shared and private data. *Private data* are used by a single processor, while *shared data* are used by multiple processors, essentially providing communication among the processors through reads and writes of the shared data. When a private item is cached, its location is migrated to the cache, reducing the average access time as well as the memory bandwidth required. Because no other processor uses the data, the program behavior is identical to that in a uniprocessor. When shared data are cached, the shared value may be replicated in multiple caches. In addition to the reduction in access latency and required memory bandwidth, this replication also provides a reduction in contention that may exist for shared data items that are being read by multiple processors simultaneously. Caching of shared data, however, introduces a new problem: cache coherence.

What Is Multiprocessor Cache Coherence?

Unfortunately, caching shared data introduces a new problem. Because the view of memory held by two different processors is through their individual caches, the processors could end up seeing different values for the same memory location, as [Figure 5.3](#) illustrates. This difficulty is generally referred to as the *cache coherence problem*. Notice that the coherence problem exists because we have both a global state, defined primarily by the main memory, and a local state, defined by the individual caches, which are private to each processor core. Thus, in a multicore where some level of caching may be shared (e.g., an L3), although some levels are private (e.g., L1 and L2), the coherence problem still exists and must be solved.

Informally, we could say that a memory system is coherent if any read of a data item returns the most recently written value of that data item. This definition,

Time	Event	Cache contents for processor A	Cache contents for processor B	Memory contents for location X
0				1
1	Processor A reads X	1		1
2	Processor B reads X	1	1	1
3	Processor A stores 0 into X	0	1	0

Figure 5.3 The cache coherence problem for a single memory location (X), read and written by two processors (A and B). We initially assume that neither cache contains the variable and that X has the value 1. We also assume a write-through cache; a write-back cache adds some additional but similar complications. After the value of X has been written by A, A’s cache and the memory both contain the new value, but B’s cache does not, and if B reads the value of X it will receive 1!

although intuitively appealing, is vague and simplistic; the reality is much more complex. This simple definition contains two different aspects of memory system behavior, both of which are critical to writing correct shared-memory programs. The first aspect, called *coherence*, defines what values can be returned by a read. The second aspect, called *consistency*, determines when a written value will be returned by a read. Let’s look at coherence first.

A memory system is coherent if

1. A read by processor P to location X that follows a write by P to X, with no writes of X by another processor occurring between the write and the read by P, always returns the value written by P.
2. A read by a processor to location X that follows a write by another processor to X returns the written value if the read and write are sufficiently separated in time and no other writes to X occur between the two accesses.
3. Writes to the same location are *serialized*; that is, two writes to the same location by any two processors are seen in the same order by all processors. For example, if the values 1 and then 2 are written to a location, processors can never read the value of the location as 2 and then later read it as 1.

The first property simply preserves program order—we expect this property to be true even in uniprocessors. The second property defines the notion of what it means to have a coherent view of memory: if a processor could continuously read an old data value, we would clearly say that memory was incoherent.

The need for write serialization is more subtle, but equally important. Suppose we did not serialize writes, and processor P1 writes location X followed by P2 writing location X. Serializing the writes ensures that every processor will see the write done by P2 at some point. If we did not serialize the writes, it might be the case that some processors could see the write of P2 first and then see the write of P1, maintaining the value written by P1 indefinitely. The simplest way

to avoid such difficulties is to ensure that all writes to the same location are seen in the same order; this property is called *write serialization*.

Although the three properties just described are sufficient to ensure coherence, the question of when a written value will be seen is also important. To see why, observe that we cannot require that a read of X instantaneously see the value written for X by some other processor. If, for example, a write of X on one processor precedes a read of X on another processor by a very small time, it may be impossible to ensure that the read returns the value of the data written, since the written data may not even have left the processor at that point. The issue of exactly *when* a written value must be seen by a reader is defined by a *memory consistency model*—a topic discussed in [Section 5.6](#).

Coherence and consistency are complementary: *Coherence defines the behavior of reads and writes to the same memory location, while consistency defines the behavior of reads and writes with respect to accesses to other memory locations.* For now, make the following two assumptions. First, a write does not complete (and allow the next write to occur) until all processors have seen the effect of that write. Second, the processor does not change the order of any write with respect to any other memory access. These two conditions mean that, if a processor writes location A followed by location B, any processor that sees the new value of B must also see the new value of A. These restrictions allow the processor to reorder reads, but forces the processor to finish a write in program order. We will rely on this assumption until we reach [Section 5.6](#), where we will see exactly the implications of this definition, as well as the alternatives.

Basic Schemes for Enforcing Coherence

The coherence problem for multiprocessors and I/O, although similar in origin, has different characteristics that affect the appropriate solution. Unlike I/O, where multiple data copies are a rare event—one to be avoided whenever possible—a program running on multiple processors will normally have copies of the same data in several caches. In a coherent multiprocessor, the caches provide both *migration* and *replication* of shared data items.

Coherent caches provide migration because a data item can be moved to a local cache and used there in a transparent fashion. This migration reduces both the latency to access a shared data item that is allocated remotely and the bandwidth demand on the shared memory.

Because the caches make a copy of the data item in the local cache, coherent caches also provide replication for shared data that are being read simultaneously. Replication reduces both latency of access and contention for a read shared data item. Supporting this migration and replication is critical to performance in accessing shared data. Thus, rather than trying to solve the problem by avoiding it in software, multiprocessors adopt a hardware solution by introducing a protocol to maintain coherent caches.

The protocols to maintain coherence for multiple processors are called *cache coherence protocols*. Key to implementing a cache coherence protocol is tracking

the state of any sharing of a data block. The state of any cache block is kept using status bits associated with the block, similar to the valid and dirty bits kept in a uniprocessor cache. There are two classes of protocols in use, each of which uses different techniques to track the sharing status:

- *Directory based*—The sharing status of a particular block of physical memory is kept in one location, called the *directory*. There are two very different types of directory-based cache coherence. In an SMP, we can use one centralized directory, associated with the memory or some other single serialization point, such as the outermost cache in a multicore. In a DSM, it makes no sense to have a single directory because that would create a single point of contention and make it difficult to scale to many multicore chips given the memory demands of multicores with eight or more cores. Distributed directories are more complex than a single directory, and such designs are the subject of [Section 5.4](#).
- *Snooping*—Rather than keeping the state of sharing in a single directory, every cache that has a copy of the data from a block of physical memory could track the sharing status of the block. In an SMP, the caches are typically all accessible via some broadcast medium (e.g., a bus connects the per-core caches to the shared cache or memory), and all cache controllers monitor or *snoop* on the medium to determine whether they have a copy of a block that is requested on a bus or switch access. Snooping can also be used as the coherence protocol for a multichip multiprocessor, and some designs support a snooping protocol on top of a directory protocol within each multicore.

Snooping protocols became popular with multiprocessors using microprocessors (single-core) and caches attached to a single shared memory by a bus. The bus provided a convenient broadcast medium to implement the snooping protocols. Multicore architectures changed the picture significantly because all multicores share some level of cache on the chip. Thus some designs switched to using directory protocols, since the overhead was small. To allow the reader to become familiar with both types of protocols, we focus on a snooping protocol here and discuss a directory protocol when we come to DSM architectures.

Snooping Coherence Protocols

There are two ways to maintain the coherence requirement described in the prior section. One method is to ensure that a processor has exclusive access to a data item before writing that item. This style of protocol is called a *write invalidate protocol* because it invalidates other copies on a write. It is by far the most common protocol. Exclusive access ensures that no other readable or writable copies of an item exist when the write occurs: all other cached copies of the item are invalidated.

[Figure 5.4](#) shows an example of an invalidation protocol with write-back caches in action. To see how this protocol ensures coherence, consider a write followed by a read by another processor: because the write requires exclusive

Processor activity	Bus activity	Contents of processor A's cache	Contents of processor B's cache	Contents of memory location X
				0
Processor A reads X	Cache miss for X	0		0
Processor B reads X	Cache miss for X	0	0	0
Processor A writes a 1 to X	Invalidation for X	1		0
Processor B reads X	Cache miss for X	1	1	1

Figure 5.4 An example of an invalidation protocol working on a snooping bus for a single cache block (X) with write-back caches. We assume that neither cache initially holds X and that the value of X in memory is 0. The processor and memory contents show the value after the processor and bus activity have both completed. A blank indicates no activity or no copy cached. When the second miss by B occurs, processor A responds with the value canceling the response from memory. In addition, both the contents of B's cache and the memory contents of X are updated. This update of memory, which occurs when a block becomes shared, simplifies the protocol, but it is possible to track the ownership and force the write-back only if the block is replaced. This requires the introduction of an additional status bit indicating ownership of a block. The ownership bit indicates that a block may be shared for reads, but only the owning processor can write the block, and that processor is responsible for updating any other processors and memory when it changes the block or replaces it. If a multicore uses a shared cache (e.g., L3), then all memory is seen through the shared cache; L3 acts like the memory in this example, and coherency must be handled for the private L1 and L2 caches for each core. It is this observation that led some designers to opt for a directory protocol within the multicore. To make this work, the L3 cache must be inclusive; recall from [Chapter 2](#), that a cache is inclusive if any location in a higher level cache (L1 and L2 in this case) is also in L3. We return to the topic of inclusion on page 423.

access, any copy held by the reading processor must be invalidated (thus the protocol name). Therefore when the read occurs, it misses in the cache and is forced to fetch a new copy of the data. For a write, we require that the writing processor has exclusive access, preventing any other processor from being able to write simultaneously. If two processors do attempt to write the same data simultaneously, one of them wins the race (we'll see how we decide who wins shortly), causing the other processor's copy to be invalidated. For the other processor to complete its write, it must obtain a new copy of the data, which must now contain the updated value. Therefore this protocol enforces write serialization.

The alternative to an invalidate protocol is to update all the cached copies of a data item when that item is written. This type of protocol is called a *write update* or *write broadcast* protocol. Because a write update protocol must broadcast all writes to shared cache lines, it consumes considerably more bandwidth. For this reason, virtually all recent multiprocessors have opted to implement a write invalidate protocol, and we will focus only on invalidate protocols for the rest of the chapter.

Basic Implementation Techniques

The key to implementing an invalidate protocol in a multicore is the use of the bus, or another broadcast medium, to perform invalidates. In older multiple-chip multiprocessors, the bus used for coherence is the shared-memory access bus. In a single-chip multicore, the bus can be the connection between the private caches (L1 and L2 in the Intel i7) and the shared outer cache (L3 in the i7). To perform an invalidate, the processor simply acquires bus access and broadcasts the address to be invalidated on the bus. All processors continuously snoop on the bus, watching the addresses. The processors check whether the address on the bus is in their cache. If so, the corresponding data in the cache are invalidated.

When a write to a block that is shared occurs, the writing processor must acquire bus access to broadcast its invalidation. If two processors attempt to write shared blocks at the same time, their attempts to broadcast an invalidate operation will be serialized when they arbitrate for the bus. The first processor to obtain bus access will cause any other copies of the block it is writing to be invalidated. If the processors were attempting to write the same block, the serialization enforced by the bus would also serialize their writes. One implication of this scheme is that a write to a shared data item cannot actually complete until it obtains bus access. All coherence schemes require some method of serializing accesses to the same cache block, either by serializing access to the communication medium or to another shared structure.

In addition to invalidating outstanding copies of a cache block that is being written into, we also need to locate a data item when a cache miss occurs. In a write-through cache, it is easy to find the recent value of a data item because all written data are always sent to the memory, from which the most recent value of a data item can always be fetched. (Write buffers can lead to some additional complexities and must effectively be treated as additional cache entries.)

For a write-back cache, the problem of finding the most recent data value is harder because the most recent value of a data item can be in a private cache rather than in the shared cache or memory. Fortunately, write-back caches can use the same snooping scheme both for cache misses and for writes: each processor snoops every address placed on the shared bus. If a processor finds that it has a dirty copy of the requested cache block, it provides that cache block in response to the read request and causes the memory (or L3) access to be aborted. The additional complexity comes from having to retrieve the cache block from another processor's private cache (L1 or L2), which can often take longer than retrieving it from L3. Because write-back caches generate lower requirements for memory bandwidth, they can support larger numbers of faster processors. As a result, all multicore processors use write-back at the outermost levels of the cache, and we will examine the implementation of coherence with write-back caches.

The normal cache tags can be used to implement the process of snooping, and the valid bit for each block makes invalidation easy to implement. Read misses, whether generated by an invalidation or by some other event, are also straightforward because they simply rely on the snooping capability. For writes, we want to know whether any other copies of the block are cached because, if there are no other cached copies, then the write does not need to be placed on the bus in a

write-back cache. Not sending the write reduces both the time to write and the required bandwidth.

To track whether or not a cache block is shared, we can add an extra state bit associated with each cache block, just as we have a valid bit and a dirty bit. By adding a bit indicating whether the block is shared, we can decide whether a write must generate an invalidate. When a write to a block in the shared state occurs, the cache generates an invalidation on the bus and marks the block as *exclusive*. No further invalidations will be sent by that core for that block. The core with the sole copy of a cache block is normally called the *owner* of the cache block.

When an invalidation is sent, the state of the owner's cache block is changed from shared to unshared (or exclusive). If another processor later requests this cache block, the state must be made shared again. Because our snooping cache also sees any misses, it knows when the exclusive cache block has been requested by another processor and the state should be made shared.

Every bus transaction must check the cache-address tags, which could potentially interfere with processor cache accesses. One way to reduce this interference is to duplicate the tags and have snoop accesses directed to the duplicate tags. Another approach is to use a directory at the shared L3 cache; the directory indicates whether a given block is shared and possibly which cores have copies. With the directory information, invalidates can be directed only to those caches with copies of the cache block. This requires that L3 must always have a copy of any data item in L1 or L2, a property called *inclusion*, which we will return to in [Section 5.7](#).

An Example Protocol

A snooping coherence protocol is usually implemented by incorporating a finite-state controller in each core. This controller responds to requests from the processor in the core and from the bus (or other broadcast medium), changing the state of the selected cache block, as well as using the bus to access data or to invalidate it. Logically, you can think of a separate controller as being associated with each block; that is, snooping operations or cache requests for different blocks can proceed independently. In actual implementations, a single controller allows multiple operations to distinct blocks to proceed in interleaved fashion (i.e., one operation may be initiated before another is completed, even though only one cache access or one bus access is allowed at a time). Also, remember that, although we refer to a bus in the following description, any interconnection network that supports a broadcast to all the coherence controllers and their associated private caches can be used to implement snooping.

The simple protocol we consider has three states: invalid, shared, and modified. The shared state indicates that the block in the private cache is potentially shared, whereas the modified state indicates that the block has been updated in the private cache; note that the modified state *implies* that the block is exclusive. [Figure 5.5](#) shows the requests generated by a core (in the top half of the table) as well as those coming from the bus (in the bottom half of the table). This protocol is for a write-back cache but is easily changed to work for a write-through cache by reinterpreting the modified state as an exclusive state and updating the cache on writes

in the normal fashion for a write-through cache. The most common extension of this basic protocol is the addition of an exclusive state, which describes a block that is unmodified but held in only one private cache. We describe this and other extensions on page 388.

Request	Source	State of addressed cache block	Type of cache action	Function and explanation
Read hit	Processor	Shared or modified	Normal hit	Read data in local cache.
Read miss	Processor	Invalid	Normal miss	Place read miss on bus.
Read miss	Processor	Shared	Replacement	Address conflict miss: place read miss on bus.
Read miss	Processor	Modified	Replacement	Address conflict miss: write-back block; then place read miss on bus.
Write hit	Processor	Modified	Normal hit	Write data in local cache.
Write hit	Processor	Shared	Coherence	Place invalidate on bus. These operations are often called upgrade or <i>ownership</i> misses, because they do not fetch the data but only change the state.
Write miss	Processor	Invalid	Normal miss	Place write miss on bus.
Write miss	Processor	Shared	Replacement	Address conflict miss: place write miss on bus.
Write miss	Processor	Modified	Replacement	Address conflict miss: write-back block; then place write miss on bus.
Read miss	Bus	Shared	No action	Allow shared cache or memory to service read miss.
Read miss	Bus	Modified	Coherence	Attempt to read shared data: place cache block on bus, write-back block, and change state to shared.
Invalidate	Bus	Shared	Coherence	Attempt to write shared block; invalidate the block.
Write miss	Bus	Shared	Coherence	Attempt to write shared block; invalidate the cache block.
Write miss	Bus	Modified	Coherence	Attempt to write block that is exclusive elsewhere; write-back the cache block and make its state invalid in the local cache.

Figure 5.5 The cache coherence mechanism receives requests from both the core's processor and the shared bus and responds to these based on the type of request, whether it hits or misses in the local cache, and the state of the local cache block specified in the request. The fourth column describes the type of cache action as normal hit or miss (the same as a uniprocessor cache would see), replacement (a uniprocessor cache replacement miss), or coherence (required to maintain cache coherence); a normal or replacement action may cause a coherence action depending on the state of the block in other caches. For read, misses, write misses, or invalidates snooped from the bus, an action is required *only* if the read or write addresses match a block in the local cache and the block is valid.

When an invalidate or a write miss is placed on the bus, any cores whose private caches have copies of the cache block invalidate it. For a write miss in a write-back cache, if the block is exclusive in just one private cache, that cache also writes back the block; otherwise, the data can be read from the shared cache or memory.

Figure 5.6 shows a finite-state transition diagram for a single private cache block using a write invalidate protocol and a write-back cache. For simplicity, the three states of the protocol are duplicated to represent transitions based on

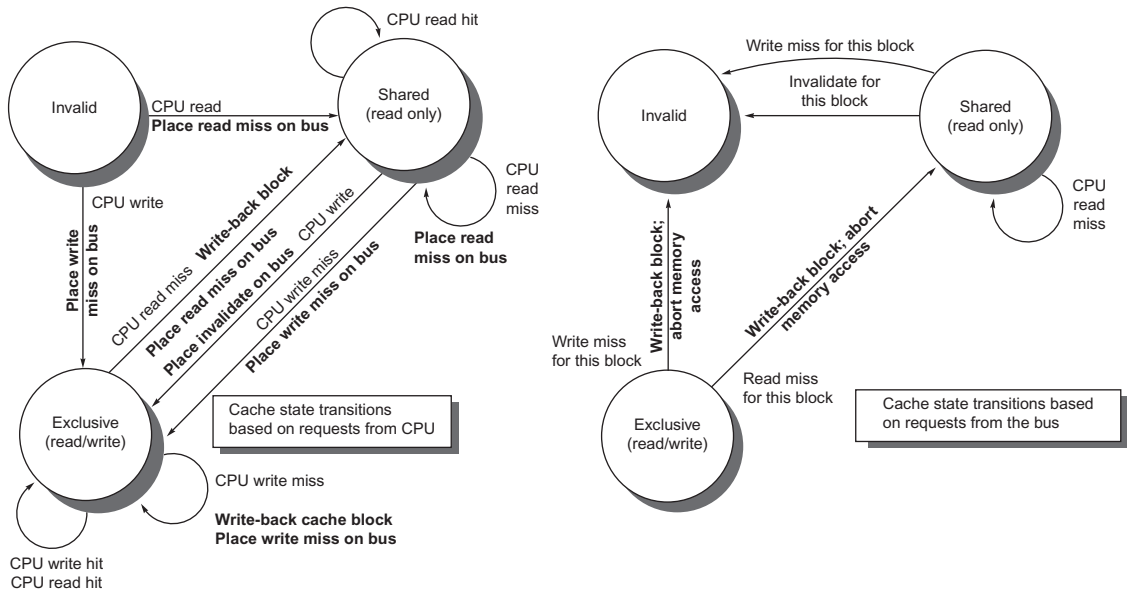

Figure 5.6 A write invalidate, cache coherence protocol for a private write-back cache showing the states and state transitions for each block in the cache. The cache states are shown in circles, with any access permitted by the local processor without a state transition shown in parentheses under the name of the state. The stimulus causing a state change is shown on the transition arcs in regular type, and any bus actions generated as part of the state transition are shown on the transition arc in *bold*. The stimulus actions apply to a block in the private cache, not to a specific address in the cache. Thus a read miss to a block in the shared state is a miss for that cache block but for a different address. The left side of the diagram shows state transitions based on actions of the processor associated with this cache; the right side shows transitions based on operations on the bus. A read miss in the exclusive or shared state and a write miss in the exclusive state occur when the address requested by the processor does not match the address in the local cache block. Such a miss is a standard cache replacement miss. An attempt to write a block in the shared state generates an invalidate. Whenever a bus transaction occurs, all private caches that contain the cache block specified in the bus transaction take the action dictated by the right half of the diagram. The protocol assumes that memory (or a shared cache) provides data on a read miss for a block that is clean in all local caches. In actual implementations, these two sets of state diagrams are combined. In practice, there are many subtle variations on invalidate protocols, including the introduction of the exclusive unmodified state, as to whether a processor or memory provides data on a miss. In a multicore chip, the shared cache (usually L3, but sometimes L2) acts as the equivalent of memory, and the bus is the bus between the private caches of each core and the shared cache, which in turn interfaces to the memory.

processor requests (on the left, which corresponds to the top half of the table in [Figure 5.5](#)), as opposed to transitions based on bus requests (on the right, which corresponds to the bottom half of the table in [Figure 5.5](#)). Boldface type is used to distinguish the bus actions, as opposed to the conditions on which a state transition depends. The state in each node represents the state of the selected private cache block specified by the processor or bus request.

All of the states in this cache protocol would be needed in a uniprocessor cache, where they would correspond to the invalid, valid (and clean), and dirty states. Most of the state changes indicated by arcs in the left half of [Figure 5.6](#) would be needed in a write-back uniprocessor cache, with the exception being the invalidate on a write hit to a shared block. The state changes represented by the arcs in the right half of [Figure 5.6](#) are needed only for coherence and would not appear at all in a uniprocessor cache controller.

As mentioned earlier, there is only one finite-state machine per cache, with stimuli coming either from the attached processor or from the bus. [Figure 5.7](#) shows how the state transitions in the right half of [Figure 5.6](#) are combined with those in the left half of the figure to form a single state diagram for each cache block.

To understand why this protocol works, observe that any valid cache block is either in the shared state in one or more private caches or in the exclusive state in exactly one cache. Any transition to the exclusive state (which is required for a processor to write to the block) requires an invalidate or write miss to be placed on the bus, causing all local caches to make the block invalid. In addition, if some other local cache had the block in exclusive state, that local cache generates a write-back, which supplies the block containing the desired address. Finally, if a read miss occurs on the bus to a block in the exclusive state, the local cache with the exclusive copy changes its state to shared.

The actions in gray in [Figure 5.7](#), which handle read and write misses on the bus, are essentially the snooping component of the protocol. One other property that is preserved in this protocol, and in most other protocols, is that any memory block in the shared state is always up to date in the outer shared cache (L2 or L3, or memory if there is no shared cache), which simplifies the implementation. In fact, it does not matter whether the level out from the private caches is a shared cache or memory; the key is that all accesses from the cores go through that level.

Although our simple cache protocol is correct, it omits a number of complications that make the implementation much trickier. The most important of these is that the protocol assumes that operations are *atomic*—that is, an operation can be done in such a way that no intervening operation can occur. For example, the protocol described assumes that write misses can be detected, acquire the bus, and receive a response as a single atomic action. In reality this is not true. In fact, even a read miss might not be atomic; after detecting a miss in the L2 of a multicore, the core must arbitrate for access to the bus connecting to the shared L3. Nonatomic actions introduce the possibility that the protocol can *deadlock*, meaning that it reaches a state where it cannot continue. We will explore these complications later in this section and when we examine DSM designs.

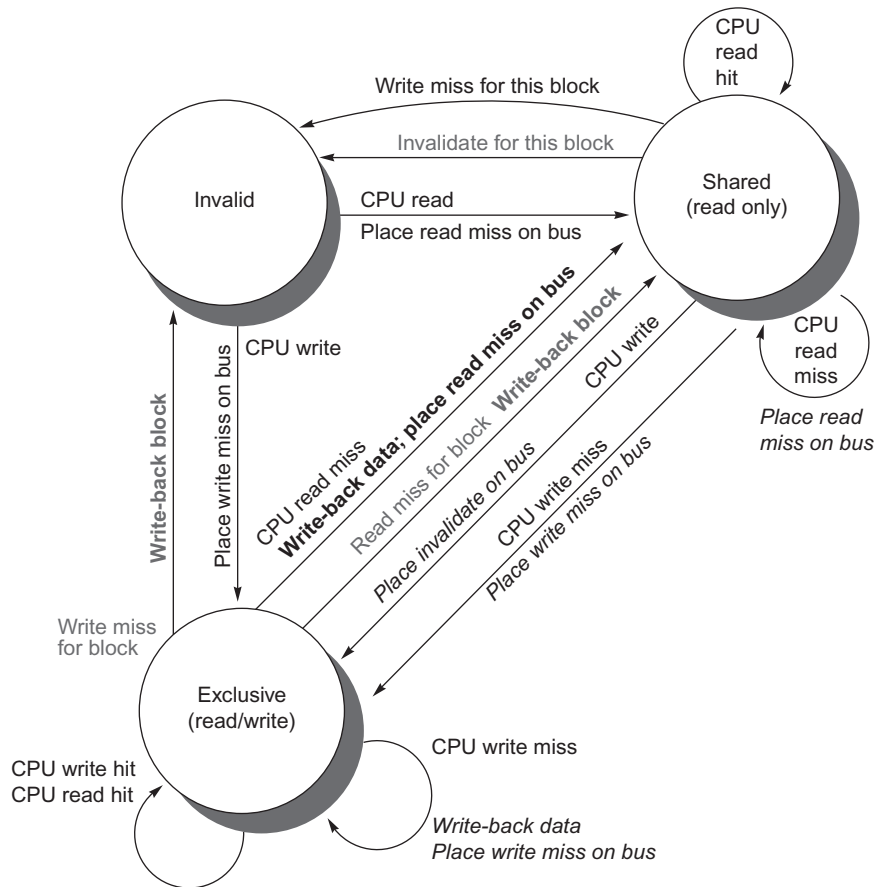

Figure 5.7 Cache coherence state diagram with the state transitions induced by the local processor shown in *black* and by the bus activities shown in *gray*. As in Figure 5.6, the activities on a transition are shown in *bold*.

With multicore processors, the coherence among the processor cores is all implemented on chip, using either a snooping or simple central directory protocol. Many multiprocessor chips, including the Intel Xeon and AMD Opteron, support multichip multiprocessors that could be built by connecting a high-speed interface already incorporated in the chip. These next-level interconnects are not just extensions of the shared bus, but use a different approach for interconnecting multicores.

A multiprocessor built with multiple multicore chips will usually have a distributed memory architecture and will need an interchip coherency mechanism above and beyond the one within the chip. In most cases, some form of directory scheme is used.

Extensions to the Basic Coherence Protocol

The coherence protocol we have just described is a simple three-state protocol and is often referred to by the first letter of the states, making it a MSI (Modified, Shared, Invalid) protocol. There are many extensions of this basic protocol, which we mention in the captions of figures in this section. These extensions are created by adding additional states and transactions that optimize certain behaviors, possibly resulting in improved performance. Two of the most common extensions are

1. *MESI* adds the state Exclusive to the basic MSI protocol, yielding four states (Modified, Exclusive, Shared, and Invalid). The exclusive state indicates that a cache block is resident in only a single cache but is clean. If a block is in the E state, it can be written without generating any invalidates, which optimizes the case where a block is read by a single cache before being written by that same cache. Of course, when a read miss to a block in the E state occurs, the block must be changed to the S state to maintain coherence. Because all subsequent accesses are snooped, it is possible to maintain the accuracy of this state. In particular, if another processor issues a read miss, the state is changed from exclusive to shared. The advantage of adding this state is that a subsequent write to a block in the exclusive state by the same core need not acquire bus access or generate an invalidate, since the block is known to be exclusively in this local cache; the processor merely changes the state to modified. This state is easily added by using the bit that encodes the coherent state as an exclusive state and using the dirty bit to indicate that a block is modified. The Intel i7 uses a variant of a MESI protocol, called MESIF, which adds a state (Forward) to designate which sharing processor should respond to a request. It is designed to enhance performance in distributed memory organizations.
2. *MOESI* adds the state Owned to the MESI protocol to indicate that the associated block is owned by that cache and out-of-date in memory. In MSI and MESI protocols, when there is an attempt to share a block in the Modified state, the state is changed to Shared (in both the original and newly sharing cache), and the block must be written back to memory. In a MOESI protocol, the block can be changed from the Modified to Owned state in the original cache without writing it to memory. Other caches, which are newly sharing the block, keep the block in the Shared state; the O state, which only the original cache holds, indicates that the main memory copy is out of date and that the designated cache is the owner. The owner of the block must supply it on a miss, since memory is not up to date and must write the block back to memory if it is replaced. The AMD Opteron processor family uses the MOESI protocol.

The next section examines the performance of these protocols for our parallel and multiprogrammed workloads; the value of these extensions to a basic protocol will be clear when we examine the performance. But, before we do that, let's take a brief look at the limitations on the use of a symmetric memory structure and a snooping coherence scheme.

Limitations in Symmetric Shared-Memory Multiprocessors and Snooping Protocols

As the number of processors in a multiprocessor grows, or as the memory demands of each processor grow, any centralized resource in the system can become a bottleneck. For multicores, a single shared bus became a bottleneck with only a few cores. As a result, multicore designs have gone to higher bandwidth interconnection schemes, as well as multiple, independent memories to allow larger numbers of cores. The multicore chips we examine in [Section 5.8](#) use three different approaches:

1. The IBM Power8, which has up to 12 processors in a single multicore, uses 8 parallel buses that connect the distributed L3 caches and up to 8 separate memory channels.
2. The Xeon E7 uses three rings to connect up to 32 processors, a distributed L3 cache, and two or four memory channels (depending on the configuration).
3. The Fujitsu SPARC64 X+ uses a crossbar to connect a shared L2 to up to 16 cores and multiple memory channels.

The SPARC64 X+ is a symmetric organization with uniform access time. The Power8 has nonuniform access time for both L3 and memory. Although the uncontended access time differences among memory addresses within a single Power8 multicore are not large, with contention for memory, the access time differences can become significant even within one chip. The Xeon E7 can operate as if access times were uniform; in practice, software systems usually organize memory so that the memory channels are associated with a subset of the cores.

Snooping bandwidth at the caches can also become a problem because every cache must examine every miss, and having additional interconnection bandwidth only pushes the problem to the cache. To understand this problem, consider the following example.

Example Consider an 8-processor multicore where each processor has its own L1 and L2 caches, and snooping is performed on a shared bus among the L2 caches. Assume the average L2 request, whether for a coherence miss or other miss, is 15 cycles. Assume a clock rate of 3.0 GHz, a CPI of 0.7, and a load/store frequency of 40%. If our goal is that no more than 50% of the L2 bandwidth is consumed by coherence traffic, what is the maximum coherence miss rate per processor?

Answer Start with an equation for the number of cache cycles that can be used (where CMR is the coherence miss rate):

$$\begin{aligned}
\text{Cache cycles available} &= \frac{\text{Clock rate}}{\text{Cycles per request} \times 2} = \frac{3.0\text{Ghz}}{30} = 0.1 \times 10^9 \\
\text{Cache cycles available} &= \text{Memory references/clock/processor} \times \text{Clock rate} \\
&\quad \times \text{processor count} \times \text{CMR} \\
&= \frac{0.4}{0.7} \times 3.0\text{GHz} \times 8 \times \text{CMR} = 13.7 \times 10^9 \times \text{CMR} \\
\text{CMR} &= \frac{0.1}{13.7} = 0.0073 = 0.73\%
\end{aligned}$$

This means that the coherence miss rate must be 0.73% or less. In the next section, we will see several applications with coherence miss rates in excess of 1%. Alternatively, if we assume that CMR can be 1%, then we could support just under 6 processors. Clearly, even small multicores will require a method for scaling snoop bandwidth.

There are several techniques for increasing the snoop bandwidth:

1. As mentioned earlier, the tags can be duplicated. This doubles the effective cache-level snoop bandwidth. If we assume that half the coherence requests do not hit on a snoop request and the cost of the snoop request is only 10 cycles (versus 15), then we can cut the average cost of a CMR to 12.5 cycles. This reduction allows the coherence miss rate to be 0.88, or alternatively to support one additional processor (7 versus 6).
2. If the outermost cache on a multicore (typically L3) is shared, we can distribute that cache so that each processor has a portion of the memory and handles snoops for that portion of the address space. This approach, used by the IBM 12-core Power8, leads to a NUCA design, but effectively scales the snoop bandwidth at L3 by the number of processors. If there is a snoop hit in L3, then we must still broadcast to all L2 caches, which must in turn snoop their contents. Since L3 is acting as a filter on the snoop requests, L3 must be inclusive.
3. We can place a directory at the level of the outermost shared cache (say, L3). L3 acts as a filter on snoop requests and must be inclusive. The use of a directory at L3 means that we need not snoop or broadcast to all the L2 caches, but only those that the directory indicates may have a copy of the block. Just as L3 may be distributed, the associated directory entries may also be distributed. This approach is used in the Intel Xeon E7 series, which supports from 8 to 32 cores.

Figure 5.8 shows how a multicore with a distributed cache system, such as that used in schemes 2 or 3, might look. If additional multicore chips were added to form a larger multiprocessor, an off-chip network would be needed, as well as a method to extend the coherence mechanisms (as we will see in [Section 5.8](#)).

Figure 5.8 A single-chip multicore with a distributed cache. In current designs, the distributed shared cache is usually L3, and levels L1 and L2 are private. There are typically multiple memory channels (2–8 in today’s designs). This design is NUCA, since the access time to L3 portions varies with faster access time for the directly attached core. Because it is NUCA, it is also NUMA.

The AMD Opteron represents another intermediate point in the spectrum between a snooping and a directory protocol. Memory is directly connected to each multicore chip, and up to four multicore chips can be connected. The system is a NUMA because local memory is somewhat faster. The Opteron implements its coherence protocol using the point-to-point links to broadcast up to three other chips. Because the interprocessor links are not shared, the only way a processor can know when an invalid operation has completed is by an explicit acknowledgment. Thus the coherence protocol uses a broadcast to find potentially shared copies, like a snooping protocol, but uses the acknowledgments to order operations, like a directory protocol. Because local memory is only somewhat faster than remote memory in the Opteron implementation, some software treats the Opteron multiprocessor as having uniform memory access.

In [Section 5.4](#), we examine directory-based protocols, which eliminate the need for broadcast to all caches on a miss. Some multicore designs use directories

within the multicore (Intel Xeon E7), while others add directories when scaling beyond a multicore. Distributed directories eliminate the need for a single point to serialize all accesses (typically a single shared bus in a snooping scheme), and any scheme that removes the single point of serialization must deal with many of the same challenges as a distributed directory scheme.

Implementing Snooping Cache Coherence

The devil is in the details.

Classic proverb

When we wrote the first edition of this book in 1990, our final “Putting It All Together” was a 30-processor, single-bus multiprocessor using snoop-based coherence; the bus had a capacity of just over 50 MiB/s, which would not be enough bus bandwidth to support even one core of an Intel i7 in 2017! When we wrote the second edition of this book in 1995, the first cache coherence multiprocessors with more than a single bus had recently appeared, and we added an appendix describing the implementation of snooping in a system with multiple buses. In 2017, *every* multicore multiprocessor system that supports 8 or more cores uses an interconnect other than a single bus, and designers must face the challenge of implementing snooping (or a directory scheme) without the simplification of a bus to serialize events.

As we observed on page 386, the major complication in actually implementing the snooping coherence protocol we have described is that write and upgrade misses are not atomic in any recent multiprocessor. The steps of detecting a write or upgrade miss, communicating with the other processors and memory, getting the most recent value for a write miss and ensuring that any invalidates are processed, and updating the cache cannot be done as though they took a single cycle.

In a multicore with a single bus, these steps can be made effectively atomic by arbitrating for the bus to the shared cache or memory first (before changing the cache state) and not releasing the bus until all actions are complete. How can the processor know when all the invalidates are complete? In early designs, a single line was used to signal when all necessary invalidates had been received and were being processed. Following that signal, the processor that generated the miss could release the bus, knowing that any required actions would be completed before any activity related to the next miss. By holding the bus exclusively during these steps, the processor effectively made the individual steps atomic.

In a system without a single, central bus, we must find some other method of making the steps in a miss atomic. In particular, we must ensure that two processors that attempt to write the same block at the same time, a situation which is called a *race*, are strictly ordered: one write is processed and precedes before the next is begun. It does not matter which of two writes in a race wins the race, just that there be only a single winner whose coherence actions are completed first. In a multicore

using multiple buses, races can be eliminated if each block of memory is associated with only a single bus, ensuring that two attempts to access the same block must be serialized by that common bus. This property, together with the ability to restart the miss handling of the loser in a race, are the keys to implementing snooping cache coherence without a bus. We explain the details in Appendix I.

It is possible to combine snooping and directories, and several designs use snooping within a multicore and directories among multiple chips or a combination of directories at one cache level and snooping at another level.

5.3

Performance of Symmetric Shared-Memory Multiprocessors

In a multicore using a snooping coherence protocol, several different phenomena combine to determine performance. In particular, the overall cache performance is a combination of the behavior of uniprocessor cache miss traffic and the traffic caused by communication, which results in invalidations and subsequent cache misses. Changing the processor count, cache size, and block size can affect these two components of the miss rate in different ways, leading to overall system behavior that is a combination of the two effects.

[Appendix B](#) breaks the uniprocessor miss rate into the three C's classification (capacity, compulsory, and conflict) and provides insight into both application behavior and potential improvements to the cache design. Similarly, the misses that arise from interprocessor communication, which are often called *coherence misses*, can be broken into two separate sources.

The first source is the *true sharing misses* that arise from the communication of data through the cache coherence mechanism. In an invalidation-based protocol, the first write by a processor to a shared cache block causes an invalidation to establish ownership of that block. Additionally, when another processor attempts to read a modified word in that cache block, a miss occurs and the resultant block is transferred. Both these misses are classified as true sharing misses because they directly arise from the sharing of data among processors.

The second effect, called *false sharing*, arises from the use of an invalidation-based coherence algorithm with a single valid bit per cache block. False sharing occurs when a block is invalidated (and a subsequent reference causes a miss) because some word in the block, other than the one being read, is written into. If the word written into is actually used by the processor that received the invalidate, then the reference was a true sharing reference and would have caused a miss independent of the block size. If, however, the word being written and the word read are different and the invalidation does not cause a new value to be communicated, but only causes an extra cache miss, then it is a false sharing miss. In a false sharing miss, the block is shared, but no word in the cache is actually shared, and the miss would not occur if the block size were a single word. The following example makes the sharing patterns clear.

Example Assume that words z1 and z2 are in the same cache block, which is in the shared state in the caches of both P1 and P2. Assuming the following sequence of events, identify each miss as a true sharing miss, a false sharing miss, or a hit. Any miss that would occur if the block size were one word is designated a true sharing miss.

Time	P1	P2
1	Write z1	
2		Read z2
3	Write z1	
4		Write z2
5	Read z2	

Answer Here are the classifications by time step:

1. This event is a true sharing miss, since z1 is in the shared state in P2 and needs to be invalidated from P2.
2. This event is a false sharing miss, since z2 was invalidated by the write of z1 in P1, but that value of z1 is not used in P2.
3. This event is a false sharing miss, since the block containing z1 is marked shared due to the read in P2, but P2 did not read z1. The cache block containing z1 will be in the shared state after the read by P2; a write miss is required to obtain exclusive access to the block. In some protocols, this will be handled as an *upgrade request*, which generates a bus invalidate, but does not transfer the cache block.
4. This event is a false sharing miss for the same reason as step 3.
5. This event is a true sharing miss, since the value being read was written by P2.

Although we will see the effects of true and false sharing misses in commercial workloads, the role of coherence misses is more significant for tightly coupled applications that share significant amounts of user data. We examine their effects in detail in Appendix I when we consider the performance of a parallel scientific workload.

A Commercial Workload

In this section, we examine the memory system behavior of a 4-processor shared-memory multiprocessor when running an online transaction processing workload. The study we examine was done with a 4-processor Alpha system in 1998, but it remains the most comprehensive and insightful study of the performance of a multiprocessor for such workloads. We will focus on understanding the multiprocessor cache activity, and particularly the behavior in L3, where much of the traffic is coherence-related.

Cache level	Characteristic	Alpha 21164	Intel i7
L1	Size	8 KB I/8 KB D	32 KB I/32 KB D
	Associativity	Direct-mapped	8-way I/8-way D
	Block size	32 B	64 B
	Miss penalty	7	10
L2	Size	96 KB	256 KB
	Associativity	3-way	8-way
	Block size	32 B	64 B
	Miss penalty	21	35
L3	Size	2 MiB (total 8 MiB unshared)	2 MiB per core (8 MiB total shared)
	Associativity	Direct-mapped	16-way
	Block size	64 B	64 B
	Miss penalty	80	~100

Figure 5.9 The characteristics of the cache hierarchy of the Alpha 21164 used in this study and the Intel i7. Although the sizes are larger and the associativity is higher on the i7, the miss penalties are also higher, so the behavior may differ only slightly. Both systems have a high penalty (125 cycles or more) for a transfer required from a private cache. A key difference is that L3 is shared in the i7 versus four separate, unshared caches in the Alpha server.

The results were collected either on an AlphaServer 4100 or using a configurable simulator modeled after the AlphaServer 4100. Each processor in the AlphaServer 4100 is an Alpha 21164, which issues up to four instructions per clock and runs at 300 MHz. Although the clock rate of the Alpha processor in this system is considerably slower than processors in systems designed in 2017, the basic structure of the system, consisting of a four-issue processor and a three-level cache hierarchy, is very similar to the multicore Intel i7 and other processors, as shown in Figure 5.9. Rather than focus on the performance details, we consider data that looks at the simulated L3 behavior for L3 caches varying from 2 to 8 MiB per processor.

Although the original study considered three different workloads, we focus our attention on the online transaction-processing (OLTP) workload modeled after TPC-B (which has memory behavior similar to its newer cousin TPC-C, described in Chapter 1) and using Oracle 7.3.2 as the underlying database. The workload consists of a set of client processes that generate requests and a set of servers that handle them. The server processes consume 85% of the user time, with the remaining going to the clients. Although the I/O latency is hidden by careful tuning and enough requests to keep the processor busy, the server processes typically block for I/O after about 25,000 instructions. Overall, 71% of the execution time is spent in user mode, 18% in the operating system, and 11% idle, primarily waiting for I/O. Of the commercial applications studied, the OLTP application stresses the memory system the hardest and shows significant challenges even when evaluated with much larger L3 caches. For example, on the AlphaServer, the processors are stalled

Figure 5.10 The relative performance of the OLTP workload as the size of the L3 cache, which is set as two-way set associative, grows from 1 to 8 MiB. The idle time also grows as cache size is increased, reducing some of the performance gains. This growth occurs because, with fewer memory system stalls, more server processes are needed to cover the I/O latency. The workload could be retuned to increase the computation/communication balance, holding the idle time in check. The PAL code is a set of sequences of specialized OS-level instructions executed in privileged mode; an example is the TLB miss handler.

for approximately 90% of the cycles with memory accesses occupying almost half the stall time and L2 misses 25% of the stall time.

We start by examining the effect of varying the size of the L3 cache. In these studies, the L3 cache is varied from 1 to 8 MiB per processor; at 2 MiB per processor, the total size of L3 is equal to that of the Intel i7 6700. In the case of the i7, however, the cache is shared, which provides both some advantages and disadvantages. It is unlikely that the shared 8 MiB cache will outperform separate L3 caches with a total size of 16 MiB. [Figure 5.10](#) shows the effect of increasing the cache size, using two-way set associative caches, which reduces the large number of conflict misses. The execution time is improved as the L3 cache grows because of the reduction in L3 misses. Surprisingly, almost all of the gain occurs in going from 1 to 2 MiB (or 4 to 8 MiB of total cache for the four processors). There is little additional gain beyond that, despite the fact that cache misses are still a cause of significant performance loss with 2 MiB and 4 MiB caches. The question is, Why?

To better understand the answer to this question, we need to determine what factors contribute to the L3 miss rate and how they change as the L3 cache grows. [Figure 5.11](#) shows these data, displaying the number of memory access cycles contributed per instruction from five sources. The two largest sources of L3 memory access cycles with a 1 MiB L3 are instruction and capacity/conflict misses. With a larger L3, these two sources shrink to be minor contributors. Unfortunately, the

Figure 5.11 The contributing causes of memory access cycle shift as the cache size is increased. The L3 cache is simulated as two-way set associative.

compulsory, false sharing, and true sharing misses are unaffected by a larger L3. Thus, at 4 and 8 MiB, the true sharing misses generate the dominant fraction of the misses; the lack of change in true sharing misses leads to the limited reductions in the overall miss rate when increasing the L3 cache size beyond 2 MiB.

Increasing the cache size eliminates most of the uniprocessor misses while leaving the multiprocessor misses untouched. How does increasing the processor count affect different types of misses? Figure 5.12 shows these data assuming a base configuration with a 2 MiB, two-way set associative L3 cache (the same effective per processor cache size as the i7 but with less associativity). As we might expect, the increase in the true sharing miss rate, which is not compensated for by any decrease in the uniprocessor misses, leads to an overall increase in the memory access cycles per instruction.

The final question we examine is whether increasing the block size—which should decrease the instruction and cold miss rate and, within limits, also reduce the capacity/conflict miss rate and possibly the true sharing miss rate—is helpful for this workload. Figure 5.13 shows the number of misses per 1000 instructions as the block size is increased from 32 to 256 bytes. Increasing the block size from 32 to 256 bytes affects four of the miss rate components:

- The true sharing miss rate decreases by more than a factor of 2, indicating some locality in the true sharing patterns.

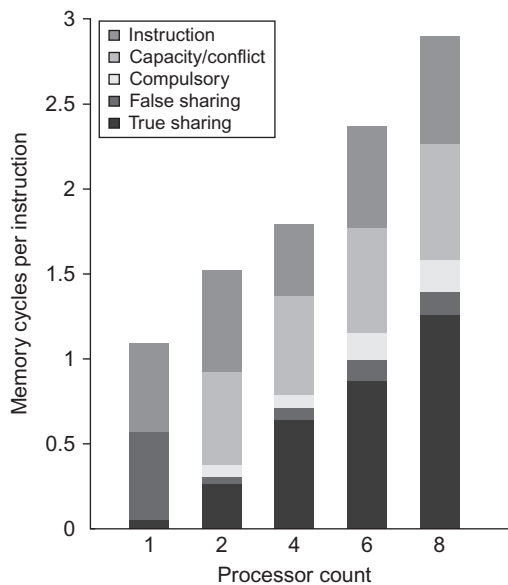

Figure 5.12 The contribution to memory access cycles increases as processor count increases primarily because of increased true sharing. The compulsory misses slightly increase because each processor must now handle more compulsory misses.

Figure 5.13 The number of misses per 1000 instructions drops steadily as the block size of the L3 cache is increased, making a good case for an L3 block size of at least 128 bytes. The L3 cache is 2 MiB, two-way set associative.

- The compulsory miss rate significantly decreases, as we would expect.
- The conflict/capacity misses show a small decrease (a factor of 1.26 compared to a factor of 8 increase in block size), indicating that the spatial locality is not high in the uniprocessor misses that occur with L3 caches larger than 2 MiB.
- The false sharing miss rate, although small in absolute terms, nearly doubles.

The lack of a significant effect on the instruction miss rate is startling. If there were an instruction-only cache with this behavior, we would conclude that the spatial locality is very poor. In the case of mixed L2 and L3 caches, other effects such as instruction-data conflicts may also contribute to the high instruction cache miss rate for larger blocks. Other studies have documented the low spatial locality in the instruction stream of large database and OLTP workloads, which have lots of short basic blocks and special-purpose code sequences. Based on these data, the miss penalty for a larger block size L3 to perform as well as the 32-byte block size L3 can be expressed as a multiplier on the 32-byte block size penalty.

Block size	Miss penalty relative to 32-byte block miss penalty
64 bytes	1.19
128 bytes	1.36
256 bytes	1.52

With modern DDR SDRAMs that make block access fast, these numbers are attainable, especially at the 64 byte (the i7 block size) and the 128 byte block size. Of course, we must also worry about the effects of the increased traffic to memory and possible contention for the memory with other cores. This latter effect may easily negate the gains obtained from improving the performance of a single processor.

A Multiprogramming and OS Workload

Our next study is a multiprogrammed workload consisting of both user activity and OS activity. The workload used is two independent copies of the compile phases of the Andrew benchmark, a benchmark that emulates a software development environment. The compile phase consists of a parallel version of the UNIX “make” command executed using eight processors. The workload runs for 5.24 seconds on eight processors, creating 203 processes and performing 787 disk requests on three different file systems. The workload is run with 128 MiB of memory, and no paging activity takes place.

The workload has three distinct phases: compiling the benchmarks, which involves substantial compute activity; installing the object files in a library; and removing the object files. The last phase is completely dominated by I/O, and only two processes are active (one for each of the runs). In the middle phase, I/O also

plays a major role, and the processor is largely idle. The overall workload is much more system- and I/O-intensive than the OLTP workload.

For the workload measurements, we assume the following memory and I/O systems:

- *Level 1 instruction cache*—32 KB, two-way set associative with a 64-byte block, 1 clock cycle hit time.
- *Level 1 data cache*—32 KB, two-way set associative with a 32-byte block, 1 clock cycle hit time. Our focus is on examining the behavior in the Level 1 data cache, in contrast to the OLTP study, which focused on the L3 cache.
- *Level 2 cache*—1 MiB unified, two-way set associative with a 128-byte block, 10 clock cycle hit time.
- *Main memory*—Single memory on a bus with an access time of 100 clock cycles.
- *Disk system*—Fixed-access latency of 3 ms (less than normal to reduce idle time).

Figure 5.14 shows how the execution time breaks down for the eight processors using the parameters just listed. Execution time is broken down into four components:

1. *Idle*—Execution in the kernel mode idle loop
2. *User*—Execution in user code
3. *Synchronization*—Execution or waiting for synchronization variables
4. *Kernel*—Execution in the OS that is neither idle nor in synchronization access

This multiprogramming workload has a significant instruction cache performance loss, at least for the OS. The instruction cache miss rate in the OS for a 64-byte block size, two-way set associative cache varies from 1.7% for a 32 KB

	User execution	Kernel execution	Synchronization wait	Processor idle (waiting for I/O)
Instructions executed	27%	3%	1%	69%
Execution time	27%	7%	2%	64%

Figure 5.14 The distribution of execution time in the multiprogrammed parallel “make” workload. The high fraction of idle time is due to disk latency when only one of the eight processors is active. These data and the subsequent measurements for this workload were collected with the SimOS system (Rosenblum et al., 1995). The actual runs and data collection were done by M. Rosenblum, S. Herrod, and E. Bugnion of Stanford University.

cache to 0.2% for a 256 KB cache. User-level instruction cache misses are roughly one-sixth of the OS rate, across the variety of cache sizes. This partially accounts for the fact that, although the user code executes nine times as many instructions as the kernel, those instructions take only about four times as long as the smaller number of instructions executed by the kernel.

Performance of the Multiprogramming and OS Workload

In this section, we examine the cache performance of the multiprogrammed workload as the cache size and block size are changed. Because of differences between the behavior of the kernel and that of the user processes, we keep these two components separate. Remember, though, that the user processes execute more than eight times as many instructions, so the overall miss rate is determined primarily by the miss rate in user code, which as we will see, is often one-fifth of the kernel miss rate.

Although the user code executes more instructions, the behavior of the operating system can cause more cache misses than the user processes for two reasons beyond larger code size and lack of locality. First, the kernel initializes all pages before allocating them to a user, which significantly increases the compulsory component of the kernel's miss rate. Second, the kernel actually shares data and thus has a nontrivial coherence miss rate. In contrast, user processes cause coherence misses only when the process is scheduled on a different processor, and this component of the miss rate is small. This is a major difference between a multiprogrammed workload and one like the OLTP workload.

Figure 5.15 shows the data miss rate versus data cache size and versus block size for the kernel and user components. Increasing the data cache size affects the user miss rate more than it affects the kernel miss rate. Increasing the block size has beneficial effects for both miss rates because a larger fraction of the misses arise from compulsory and capacity, both of which can be potentially improved with larger block sizes. Because coherence misses are relatively rarer, the negative effects of increasing block size are small. To understand why the kernel and user processes behave differently, we can look at how the kernel misses behave.

Figure 5.16 shows the variation in the kernel misses versus increases in cache size and in block size. The misses are broken into three classes: compulsory misses, coherence misses (from both true and false sharing), and capacity/conflict misses (which include misses caused by interference between the OS and the user process and between multiple user processes). Figure 5.16 confirms that, for the kernel references, increasing the cache size reduces only the uniprocessor capacity/conflict miss rate. In contrast, increasing the block size causes a reduction in the compulsory miss rate. The absence of large increases in the coherence miss rate as block size is increased means that false sharing effects are probably insignificant, although such misses may be offsetting some of the gains from reducing the true sharing misses.

If we examine the number of bytes needed per data reference, as in Figure 5.17, we see that the kernel has a higher traffic ratio that grows with block size. It is easy to see why this occurs: when going from a 16-byte block to a 128-byte block, the

Figure 5.15 The data miss rates for the user and kernel components behave differently for increases in the L1 data cache size (on the left) versus increases in the L1 data cache block size (on the right). Increasing the L1 data cache from 32 to 256 KB (with a 32-byte block) causes the user miss rate to decrease proportionately more than the kernel miss rate: the user-level miss rate drops by almost a factor of 3, whereas the kernel-level miss rate drops by a factor of only 1.3. At the largest size, the L1 is closer to the size of L2 in a modern multicore processors. Thus the data indicates that the kernel miss rate will still be significant in an L2 cache. The miss rate for both user and kernel components drops steadily as the L1 block size is increased (while keeping the L1 cache at 32 KB). In contrast to the effects of increasing the cache size, increasing the block size improves the kernel miss rate more significantly (just under a factor of 4 for the kernel references when going from 16-byte to 128-byte blocks versus just under a factor of 3 for the user references).

Figure 5.16 The components of the kernel data miss rate change as the L1 data cache size is increased from 32 to 256 KB, when the multiprogramming workload is run on eight processors. The compulsory miss rate component stays constant because it is unaffected by cache size. The capacity component drops by more than a factor of 2, whereas the coherence component nearly doubles. The increase in coherence misses occurs because the probability of a miss being caused by an invalidation increases with cache size, since fewer entries are bumped due to capacity. As we would expect, the increasing block size of the L1 data cache substantially reduces the compulsory miss rate in the kernel references. It also has a significant impact on the capacity miss rate, decreasing it by a factor of 2.4 over the range of block sizes. The increased block size has a small reduction in coherence traffic, which appears to stabilize at 64 bytes, with no change in the coherence miss rate in going to 128-byte lines. Because there are no significant reductions in the coherence miss rate as the block size increases, the fraction of the miss rate caused by coherence grows from about 7% to about 15%.

Figure 5.17 The number of bytes needed per data reference grows as block size is increased for both the kernel and user components. It is interesting to compare this chart with the data on scientific programs shown in Appendix I.

miss rate drops by about 3.7, but the number of bytes transferred per miss increases by 8, so the total miss traffic increases by just over a factor of 2. The user program also more than doubles as the block size goes from 16 to 128 bytes, but it starts out at a much lower level.

For the multiprogrammed workload, the OS is a much more demanding user of the memory system. If more OS or OS-like activity is included in the workload, and the behavior is similar to what was measured for this workload, it will become very difficult to build a sufficiently capable memory system. One possible route to improving performance is to make the OS more cache-aware through either better programming environments or through programmer assistance. For example, the OS reuses memory for requests that arise from different system calls. Despite the fact that the reused memory will be completely overwritten, the hardware, not recognizing this, will attempt to preserve coherency and the possibility that some portion of a cache block may be read, even if it is not. This behavior is analogous to the reuse of stack locations on procedure invocations. The IBM Power series has support to allow the compiler to indicate this type of behavior on procedure invocations, and the newest AMD processors have similar support. It is harder to detect such behavior by the OS, and doing so may require programmer assistance, but the payoff is potentially even greater.

OS and commercial workloads pose tough challenges for multiprocessor memory systems, and unlike scientific applications, which we examine in Appendix I, they are less amenable to algorithmic or compiler restructuring. As the number of cores increases, predicting the behavior of such applications is likely to get more difficult. Emulation or simulation methodologies that allow the simulation of tens

to hundreds of cores with large applications (including operating systems) will be crucial to maintaining an analytical and quantitative approach to design.

5.4

Distributed Shared-Memory and Directory-Based Coherence

As we saw in [Section 5.2](#), a snooping protocol requires communication with all caches on every cache miss, including writes of potentially shared data. The absence of any centralized data structure that tracks the state of the caches is both the fundamental advantage of a snooping-based scheme, since it allows it to be inexpensive, as well as its Achilles' heel when it comes to scalability.

For example, consider a multiprocessor consisting of four 4-core multicores capable of sustaining one data reference per clock and a 4 GHz clock. From the data in [Section I.5](#) in [Appendix I](#), we can see that the applications may require 4–170 GiB/s of memory bus bandwidth. The maximum memory bandwidth supported by the i7 with two DDR4 memory channels is 34 GiB/s. If several i7 multicore processors shared the same memory system, they would easily swamp it. In the last few years, the development of multicore processors forced all designers to shift to some form of distributed memory to support the bandwidth demands of the individual processors.

We can increase the memory bandwidth and interconnection bandwidth by distributing the memory, as shown in [Figure 5.2](#) on page 373; this immediately separates local memory traffic from remote memory traffic, reducing the bandwidth demands on the memory system and on the interconnection network. Unless we eliminate the need for the coherence protocol to broadcast on every cache miss, distributing the memory will gain us little.

As we mentioned earlier, the alternative to a snooping-based coherence protocol is a *directory protocol*. A directory keeps the state of every block that may be cached. Information in the directory includes which caches (or collections of caches) have copies of the block, whether it is dirty, and so on. Within a multicore with a shared outermost cache (say, L3), it is easy to implement a directory scheme: simply keep a bit vector of the size equal to the number of cores for each L3 block. The bit vector indicates which private L2 caches may have copies of a block in L3, and invalidations are sent only to those caches. This works perfectly for a single multicore if L3 is inclusive, and this scheme is the one used in the Intel i7.

The solution of a single directory used in a multicore is not scalable, even though it avoids broadcast. The directory must be distributed, but the distribution must be done in a way that the coherence protocol knows where to find the directory information for any cached block of memory. The obvious solution is to distribute the directory along with the memory so that different coherence requests can go to different directories, just as different memory requests go to different memories. If the information is maintained at an outer cache, like L3, which is multibanked, the directory information can be distributed with the different cache banks, effectively increasing the bandwidth.

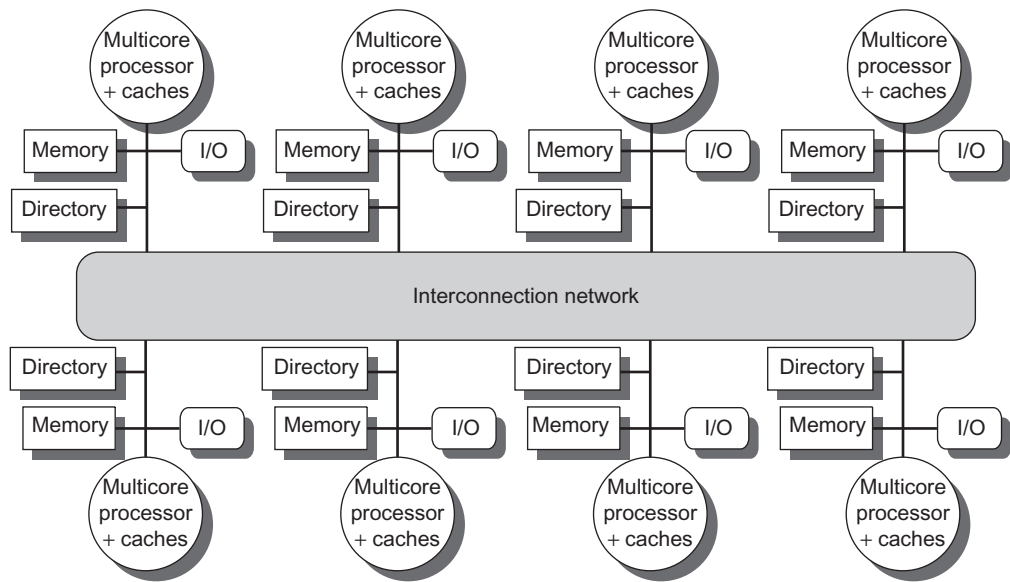

Figure 5.18 A directory is added to each node to implement cache coherence in a distributed-memory multiprocessor. In this case, a node is shown as a single multicore chip, and the directory information for the associated memory may reside either on or off the multicore. Each directory is responsible for tracking the caches that share the memory addresses of the portion of memory in the node. The coherence mechanism will handle both the maintenance of the directory information and any coherence actions needed within the multicore node.

A distributed directory retains the characteristic that the sharing status of a block is always in a single known location. This property, together with the maintenance of information that says what other nodes may be caching the block, is what allows the coherence protocol to avoid broadcast. Figure 5.18 shows how our distributed-memory multiprocessor looks with the directories added to each node.

The simplest directory implementations associate an entry in the directory with each memory block. In such implementations, the amount of information is proportional to the product of the number of memory blocks (where each block is the same size as the L2 or L3 cache block) times the number of nodes, where a node is a single multicore processor or a small collection of processors that implements coherence internally. This overhead is not a problem for multiprocessors with less than a few hundred processors (each of which might be a multicore) because the directory overhead with a reasonable block size will be tolerable. For larger multiprocessors, we need methods to allow the directory structure to be efficiently scaled, but only supercomputer-sized systems need to worry about this.

Directory-Based Cache Coherence Protocols: The Basics

Just as with a snooping protocol, there are two primary operations that a directory protocol must implement: handling a read miss and handling a write to a shared, clean cache block. (Handling a write miss to a block that is currently shared is a simple combination of these two.) To implement these operations, a directory must track the state of each cache block. In a simple protocol, these states could be the following:

- *Shared*—One or more nodes have the block cached, and the value in memory is up to date (as well as in all the caches).
- *Uncached*—No node has a copy of the cache block.
- *Modified*—Exactly one node has a copy of the cache block, and it has written the block, so the memory copy is out of date. The processor is called the *owner* of the block.

In addition to tracking the state of each potentially shared memory block, we must track which nodes have copies of that block because those copies will need to be invalidated on a write. The simplest way to do this is to keep a bit vector for each memory block. When the block is shared, each bit of the vector indicates whether the corresponding processor chip (which is likely a multicore) has a copy of that block. We can also use the bit vector to keep track of the owner of the block when the block is in the exclusive state. For efficiency reasons, we also track the state of each cache block at the individual caches.

The states and transitions for the state machine at each cache are identical to what we used for the snooping cache, although the actions on a transition are slightly different. The processes of invalidating and locating an exclusive copy of a data item are different because they both involve communication between the requesting node and the directory and between the directory and one or more remote nodes. In a snooping protocol, these two steps are combined through the use of a broadcast to all the nodes.

Before we see the protocol state diagrams, it is useful to examine a catalog of the message types that may be sent between the processors and the directories for the purpose of handling misses and maintaining coherence. [Figure 5.19](#) shows the types of messages sent among nodes. The *local node* is the node where a request originates. The *home node* is the node where the memory location and the directory entry of an address reside. The physical address space is statically distributed, so the node that contains the memory and directory for a given physical address is known. For example, the high-order bits may provide the node number, whereas the low-order bits provide the offset within the memory on that node. The local node may also be the home node. The directory must be accessed when the home node is the local node because copies may exist in yet a third node, called a *remote node*.

Message type	Source	Destination	Message contents	Function of this message
Read miss	Local cache	Home directory	P, A	Node P has a read miss at address A; request data and make P a read sharer.
Write miss	Local cache	Home directory	P, A	Node P has a write miss at address A; request data and make P the exclusive owner.
Invalidate	Local cache	Home directory	A	Request to send invalidates to all remote caches that are caching the block at address A.
Invalidate	Home directory	Remote cache	A	Invalidate a shared copy of data at address A.
Fetch	Home directory	Remote cache	A	Fetch the block at address A and send it to its home directory; change the state of A in the remote cache to shared.
Fetch/invalidate	Home directory	Remote cache	A	Fetch the block at address A and send it to its home directory; invalidate the block in the cache.
Data value reply	Home directory	Local cache	D	Return a data value from the home memory.
Data write-back	Remote cache	Home directory	A, D	Write back a data value for address A.

Figure 5.19 The possible messages sent among nodes to maintain coherence, along with the source and destination node, the contents (where P = requesting node number, A = requested address, and D = data contents), and the function of the message. The first three messages are requests sent by the local node to the home. The fourth through sixth messages are messages sent to a remote node by the home when the home needs the data to satisfy a read or write miss request. Data value replies are used to send a value from the home node back to the requesting node. Data value write-backs occur for two reasons: when a block is replaced in a cache and must be written back to its home memory, and also in reply to fetch or fetch/invalidate messages from the home. Writing back the data value whenever the block becomes shared simplifies the number of states in the protocol because any dirty block must be exclusive and any shared block is always available in the home memory.

A remote node is the node that has a copy of a cache block, whether exclusive (in which case it is the only copy) or shared. A remote node may be the same as either the local node or the home node. In such cases, the basic protocol does not change, but interprocessor messages may be replaced with intraprocessor messages.

In this section, we assume a simple model of memory consistency. To minimize the type of messages and the complexity of the protocol, we make an assumption that messages will be received and acted upon in the same order they are sent. This assumption may not be true in practice and can result in additional complications, some of which we address in [Section 5.6](#) when we discuss memory consistency models. In this section, we use this assumption to ensure that invalidates sent by a node are honored before new messages are transmitted, just as we assumed in the discussion of implementing snooping protocols. As we did in the snooping case, we omit some details necessary to implement the coherence

protocol. In particular, the serialization of writes and knowing that the invalidates for a write have completed are not as simple as in the broadcast-based snooping mechanism. Instead, explicit acknowledgments are required in response to write misses and invalidate requests. We discuss these issues in more detail in Appendix I.

An Example Directory Protocol

The basic states of a cache block in a directory-based protocol are exactly like those in a snooping protocol, and the states in the directory are also analogous to those we showed earlier. Thus we can start with simple state diagrams that show the state transitions for an individual cache block and then examine the state diagram for the directory entry corresponding to each block in memory. As in the snooping case, these state transition diagrams do not represent all the details of a coherence protocol; however, the actual controller is highly dependent on a number of details of the multiprocessor (message delivery properties, buffering structures, and so on). In this section, we present the basic protocol state diagrams. The knotty issues involved in implementing these state transition diagrams are examined in Appendix I.

Figure 5.20 shows the protocol actions to which an individual cache responds. We use the same notation as in the last section, with requests coming from outside the node in gray and actions in bold. The state transitions for an individual cache are caused by read misses, write misses, invalidates, and data fetch requests; Figure 5.20 shows these operations. An individual cache also generates read miss, write miss, and invalidate messages that are sent to the home directory. Read and write misses require data value replies, and these events wait for replies before changing state. Knowing when invalidates complete is a separate problem and is handled separately.

The operation of the state transition diagram for a cache block in Figure 5.20 is essentially the same as it is for the snooping case: the states are identical, and the stimulus is almost identical. The write miss operation, which was broadcast on the bus (or other network) in the snooping scheme, is replaced by the data fetch and invalidate operations that are selectively sent by the directory controller. Like the snooping protocol, any cache block must be in the exclusive state when it is written, and any shared block must be up to date in memory. In many multicore processors, the outermost level in the processor cache is shared among the cores (as is the L3 in the Intel i7, the AMD Opteron, and the IBM Power7), and hardware at that level maintains coherence among the private caches of each core on the same chip, using either an internal directory or snooping. Thus the on-chip multicore coherence mechanism can be used to extend coherence among a larger set of processors simply by interfacing to the outermost shared cache. Because this interface is at L3, contention between the processor and coherence requests is less of an issue, and duplicating the tags could be avoided.

In a directory-based protocol, the directory implements the other half of the coherence protocol. A message sent to a directory causes two different types of

Figure 5.21 The state transition diagram for the directory has the same states and structure as the transition diagram for an individual cache. All actions are in gray because they are all externally caused. *Bold* indicates the action taken by the directory in response to the request.

requests need to update the set *Sharers* and also read the set to perform invalidations.

Figure 5.21 shows the actions taken at the directory in response to messages received. The directory receives three different requests: read miss, write miss, and data write-back. The messages sent in response by the directory are shown in bold, and the updating of the set *Sharers* is shown in bold italics. Because all the stimulus messages are external, all actions are shown in gray. Our simplified protocol assumes that some actions are atomic, such as requesting a value and sending it to another node; a realistic implementation cannot use this assumption.

To understand these directory operations, let's examine the requests received and actions taken state by state. When a block is in the uncached state, the copy in memory is the current value, so the only possible requests for that block are

- *Read miss*—The requesting node is sent the requested data from memory, and the requester is made the only sharing node. The state of the block is made shared.

- *Write miss*—The requesting node is sent the value and becomes the sharing node. The block is made exclusive to indicate that the only valid copy is cached. Sharers indicates the identity of the owner.

When the block is in the shared state, the memory value is up to date, so the same two requests can occur:

- *Read miss*—The requesting node is sent the requested data from memory, and the requesting node is added to the sharing set.
- *Write miss*—The requesting node is sent the value. All nodes in the set Sharers are sent invalidate messages, and the Sharers set is to contain the identity of the requesting node. The state of the block is made exclusive.

When the block is in the exclusive state, the current value of the block is held in a cache on the node identified by the set Sharers (the owner), so there are three possible directory requests:

- *Read miss*—The owner is sent a data fetch message, which causes the state of the block in the owner's cache to transition to shared and causes the owner to send the data to the directory, where it is written to memory and sent back to the requesting processor. The identity of the requesting node is added to the set Sharers, which still contains the identity of the processor that was the owner (since it still has a readable copy).
- *Data write-back*—The owner is replacing the block and therefore must write it back. This write-back makes the memory copy up to date (the home directory essentially becomes the owner), the block is now uncached, and the Sharers set is empty.
- *Write miss*—The block has a new owner. A message is sent to the old owner, causing the cache to invalidate the block and send the value to the directory, from which it is sent to the requesting node, which becomes the new owner. Sharers is set to the identity of the new owner, and the state of the block remains exclusive.

This state transition diagram in [Figure 5.21](#) is a simplification, just as it was in the snooping cache case. In the case of a directory, as well as a snooping scheme implemented with a network other than a bus, our protocols will need to deal with nonatomic memory transactions. Appendix I explores these issues in depth.

The directory protocols used in real multiprocessors contain additional optimizations. In particular, in this protocol when a read or write miss occurs for a block that is exclusive, the block is first sent to the directory at the home node. From there it is stored into the home memory and also sent to the original requesting node. Many of the protocols in use in commercial multiprocessors forward the data from the owner node to the requesting node directly (as well as performing the write-back to the home). Such optimizations often add complexity by increasing the possibility of deadlock and by increasing the types of messages that must be handled.

Implementing a directory scheme requires solving most of the same challenges we discussed for snooping protocols. There are, however, new and additional problems, which we describe in Appendix I. In [Section 5.8](#), we briefly describe how modern multicores extend coherence beyond a single chip. The combinations of multichip coherence and multicore coherence include all four possibilities of snooping/snooping (AMD Opteron), snooping/directory, directory/snooping, and directory/directory! Many multiprocessors have chosen some form of snooping within a single chip, which is attractive if the outermost cache is shared and inclusive, and directories across multiple chips. Such an approach simplifies implementation because only the processor chip, rather than an individual core, need be tracked.

5.5

Synchronization: The Basics

Synchronization mechanisms are typically built with user-level software routines that rely on hardware-supplied synchronization instructions. For smaller multiprocessors or low-contention situations, the key hardware capability is an uninterruptible instruction or instruction sequence capable of atomically retrieving and changing a value. Software synchronization mechanisms are then constructed using this capability. In this section, we focus on the implementation of lock and unlock synchronization operations. Lock and unlock can be used straightforwardly to create mutual exclusion, as well as to implement more complex synchronization mechanisms.

In high-contention situations, synchronization can become a performance bottleneck because contention introduces additional delays and because latency is potentially greater in such a multiprocessor. We discuss how the basic synchronization mechanisms of this section can be extended for large processor counts in Appendix I.

Basic Hardware Primitives

The key ability we require to implement synchronization in a multiprocessor is a set of hardware primitives with the ability to atomically read and modify a memory location. Without such a capability, the cost of building basic synchronization primitives will be too high and will increase as the processor count increases. There are a number of alternative formulations of the basic hardware primitives, all of which provide the ability to atomically read and modify a location, together with some way to tell whether the read and write were performed atomically. These hardware primitives are the basic building blocks that are used to build a wide variety of user-level synchronization operations, including things such as locks and barriers. In general, architects do not expect users to employ the basic hardware primitives, but instead expect that the primitives will be used by system programmers to build a synchronization library, a process that is often complex and tricky. Let's start with one such hardware primitive and show how it can be used to build some basic synchronization operations.

One typical operation for building synchronization operations is the *atomic exchange*, which interchanges a value in a register for a value in memory. To see how to use this to build a basic synchronization operation, assume that we want to build a simple lock where the value 0 is used to indicate that the lock is free and 1 is used to indicate that the lock is unavailable. A processor tries to set the lock by doing an exchange of 1, which is in a register, with the memory address corresponding to the lock. The value returned from the exchange instruction is 1 if some other processor had otherwise already claimed access and 0. In the latter case, the value is also changed to 1, preventing any competing exchange from also retrieving a 0.

For example, consider two processors that each try to do the exchange simultaneously: This race is broken because exactly one of the processors will perform the exchange first, returning 0, and the second processor will return 1 when it does the exchange. The key to using the exchange (or swap) primitive to implement synchronization is that the operation is atomic: the exchange is indivisible, and two simultaneous exchanges will be ordered by the write serialization mechanisms. It is impossible for two processors trying to set the synchronization variable in this manner to both determine they have simultaneously set the variable.

There are a number of other atomic primitives that can be used to implement synchronization. They all have the key property that they read and update a memory value in such a manner that we can tell whether the two operations executed atomically. One operation, present in many older multiprocessors, is *test-and-set*, which tests a value and sets it if the value passes the test. For example, we could define an operation that tested for 0 and set the value to 1, which can be used in a fashion similar to how we used atomic exchange. Another atomic synchronization primitive is *fetch-and-increment*: it returns the value of a memory location and atomically increments it. By using the value 0 to indicate that the synchronization variable is unclaimed, we can use fetch-and-increment, just as we used exchange. There are other uses of operations like fetch-and-increment, which we will see shortly.

Implementing a single atomic memory operation introduces some challenges because it requires both a memory read and a write in a single, uninterruptible instruction. This requirement complicates the implementation of coherence because the hardware cannot allow any other operations between the read and the write, and yet must not deadlock.

An alternative is to have a pair of instructions where the second instruction returns a value from which it can be deduced whether the pair of instructions was executed as though the instructions were atomic. The pair of instructions is effectively atomic if it appears as though all other operations executed by any processor occurred before or after the pair. Thus, when an instruction pair is effectively atomic, no other processor can change the value between the instruction pair. This is the approach used in the MIPS processors and in RISC V.

In RISC V, the pair of instructions includes a special load called a *load reserved* (also called load linked or *load locked*) and a special store called a *store conditional*. Load reserved loads the contents of memory given by rs1 into rd and creates a reservation on that memory address. Store conditional stores the value in rs2 into the memory address given by rs1. If the reservation of the load is broken by

a write to the same memory location, the store conditional fails and writes a non-zero to *rd*; if it succeeds, the store conditional writes 0. If the processor does a context switch between the two instructions, then the store conditional always fails.

These instructions are used in sequence, and because the load reserved returns the initial value and the store conditional returns 0 only if it succeeds, the following sequence implements an atomic exchange on the memory location specified by the contents of *x1* with the value in *x4*:

```
try:    mov    x3,x4        ;mov exchange value
        lr     x2,x1        ;load reserved from
        sc     x3,0(x1)     ;store conditional
        bnez   x3,try       ;branch store fails
        mov    x4,x2        ;put load value in x4
```

At the end of this sequence, the contents of *x4* and the memory location specified by *x1* have been atomically exchanged. Anytime a processor intervenes and modifies the value in memory between the *lr* and *sc* instructions, the *sc* returns 0 in *x3*, causing the code sequence to try again.

An advantage of the load reserved/store conditional mechanism is that it can be used to build other synchronization primitives. For example, here is an atomic fetch-and-increment:

```
try:    lr     x2,x1        ;load reserved 0(x1)
        addi   x3,x2,1      ;increment
        sc     x3,0(x1)     ;store conditional
        bnez   x3,try       ;branch store fails
```

These instructions are typically implemented by keeping track of the address specified in the *lr* instruction in a register, often called the *reserved register*. If an interrupt occurs, or if the cache block matching the address in the link register is invalidated (e.g., by another *sc*), the link register is cleared. The *sc* instruction simply checks that its address matches that in the reserved register. If so, the *sc* succeeds; otherwise, it fails. Because the store conditional will fail after either another attempted store to the load reserved address or any exception, care must be taken in choosing what instructions are inserted between the two instructions. In particular, only register-register instructions can safely be permitted; otherwise, it is possible to create deadlock situations where the processor can never complete the *sc*. In addition, the number of instructions between the load reserved and the store conditional should be small to minimize the probability that either an unrelated event or a competing processor causes the store conditional to fail frequently.

Implementing Locks Using Coherence

Once we have an atomic operation, we can use the coherence mechanisms of a multiprocessor to implement *spin locks*—locks that a processor continuously tries to acquire, spinning around a loop until it succeeds. Spin locks are used when programmers expect the lock to be held for a very short amount of time and when they want the process of locking to be low latency when the lock is available. Because

spin locks tie up the processor waiting in a loop for the lock to become free, they are inappropriate in some circumstances.

The simplest implementation, which we would use if there were no cache coherence, would be to keep the lock variables in memory. A processor could continually try to acquire the lock using an atomic operation, say, atomic exchange, and test whether the exchange returned the lock as free. To release the lock, the processor simply stores the value 0 to the lock. Here is the code sequence to lock a spin lock whose address is in `x1`. It uses `EXCH` as a macro for the atomic exchange sequence from page 414:

```

                addi  x2,R0,#1
lockit:  EXCH  x2,0(x1)      ;atomic exchange
                bnez  x2,lockit    ;already locked?
```

If our multiprocessor supports cache coherence, we can cache the locks using the coherence mechanism to maintain the lock value coherently. Caching locks has two advantages. First, it allows an implementation where the process of “spinning” (trying to test and acquire the lock in a tight loop) could be done on a local cached copy rather than requiring a global memory access on each attempt to acquire the lock. The second advantage comes from the observation that there is often locality in lock accesses; that is, the processor that used the lock last will use it again in the near future. In such cases, the lock value may reside in the cache of that processor, greatly reducing the time to acquire the lock.

Obtaining the first advantage—being able to spin on a local cached copy rather than generating a memory request for each attempt to acquire the lock—requires a change in our simple spin procedure. Each attempt to exchange in the preceding loop requires a write operation. If multiple processors are attempting to get the lock, each will generate the write. Most of these writes will lead to write misses because each processor is trying to obtain the lock variable in an exclusive state.

Thus we should modify our spin lock procedure so that it spins by doing reads on a local copy of the lock until it successfully sees that the lock is available. Then it attempts to acquire the lock by doing a swap operation. A processor first reads the lock variable to test its state. A processor keeps reading and testing until the value of the read indicates that the lock is unlocked. The processor then races against all other processes that were similarly “spin waiting” to see which can lock the variable first. All processes use a swap instruction that reads the old value and stores a 1 into the lock variable. The single winner will see the 0, and the losers will see a 1 that was placed there by the winner. (The losers will continue to set the variable to the locked value, but that doesn’t matter.) The winning processor executes the code after the lock and, when finished, stores a 0 into the lock variable to release the lock, which starts the race all over again. Here is the code to perform this spin lock (remember that 0 is unlocked and 1 is locked):

```

lockit:  ld      x2,0(x1)      ;load of lock
                bnez  x2,lockit  ;not available-spin
                addi  x2,R0,#1    ;load locked value
                EXCH  x2,0(x1)    ;swap
                bnez  x2,lockit    ;branch if lock wasn't 0
```

Step	P0	P1	P2	Coherence state of lock at end of step	Bus/directory activity
1	Has lock	Begins spin, testing if lock = 0	Begins spin, testing if lock = 0	Shared	Cache misses for P1 and P2 satisfied in either order. Lock state becomes shared.
2	Set lock to 0	(Invalidate received)	(Invalidate received)	Exclusive (P0)	Write invalidate of lock variable from P0.
3		Cache miss	Cache miss	Shared	Bus/directory services P2 cache miss; write-back from P0; state shared.
4		(Waits while bus/directory busy)	Lock = 0 test succeeds	Shared	Cache miss for P2 satisfied.
5		Lock = 0	Executes swap, gets cache miss	Shared	Cache miss for P1 satisfied.
6		Executes swap, gets cache miss	Completes swap: returns 0 and sets lock = 1	Exclusive (P2)	Bus/directory services P2 cache miss; generates invalidate; lock is exclusive.
7		Swap completes and returns 1, and sets lock = 1	Enter critical section	Exclusive (P1)	Bus/directory services P1 cache miss; sends invalidate and generates write-back from P2.
8		Spins, testing if lock = 0			None

Figure 5.22 Cache coherence steps and bus traffic for three processors, P0, P1, and P2. This figure assumes write invalidate coherence. P0 starts with the lock (step 1), and the value of the lock is 1 (i.e., locked); it is initially exclusive and owned by P0 before step 1 begins. P0 exits and unlocks the lock (step 2). P1 and P2 race to see which reads the unlocked value during the swap (steps 3–5). P2 wins and enters the critical section (steps 6 and 7), while P1’s attempt fails, so it starts spin waiting (steps 7 and 8). In a real system, these events will take many more than 8 clock ticks because acquiring the bus and replying to misses take much longer. Once step 8 is reached, the process can repeat with P2, eventually getting exclusive access and setting the lock to 0.

Let’s examine how this “spin lock” scheme uses the cache coherence mechanisms. Figure 5.22 shows the processor and bus or directory operations for multiple processes trying to lock a variable using an atomic swap. Once the processor with the lock stores a 0 into the lock, all other caches are invalidated and must fetch the new value to update their copy of the lock. One such cache gets the copy of the unlocked value (0) first and performs the swap. When the cache miss of other processors is satisfied, they find that the variable is already locked, so they must return to testing and spinning.

This example shows another advantage of the load reserved/store conditional primitives: the read and write operations are explicitly separated. The load reserved need not cause any bus traffic. This fact allows the following simple code sequence, which has the same characteristics as the optimized version using exchange (`x1` has the address of the lock, the `l r` has replaced the `LD`, and the `sc` has replaced the `EXCH`):

```

lockit:  lr    x2,0(x1)    ;load reserved
        bnez  x2,lockit   ;not available-spin
        addi  x2,R0,#1    ;locked value
        sc    x2,0(x1)    ;store
        bnez  x2,lockit   ;branch if store fails

```

The first branch forms the spinning loop; the second branch resolves races when two processors see the lock available simultaneously.

5.6

Models of Memory Consistency: An Introduction

Cache coherence ensures that multiple processors see a consistent view of memory. It does not answer the question of *how* consistent the view of memory must be. By “how consistent,” we are really asking when a processor must see a value that has been updated by another processor. Because processors communicate through shared variables (used both for data values and for synchronization), the question boils down to this: In what order must a processor observe the data writes of another processor? Because the only way to “observe the writes of another processor” is through reads, the question becomes what properties must be enforced among reads and writes to different locations by different processors?

Although the question of how consistent memory must be seems simple, it is remarkably complicated, as we can see with a simple example. Here are two code segments from processes P1 and P2, shown side by side:

P1:	A = 0;	P2:	B = 0;

	A = 1;		B = 1;
L1:	if (B == 0)...	L2:	if (A == 0)...

Assume that the processes are running on different processors, and that locations A and B are originally cached by both processors with the initial value of 0. If writes always take immediate effect and are immediately seen by other processors, it will be impossible for *both* IF statements (labeled L1 and L2) to evaluate their conditions as true, since reaching the IF statement means that either A or B must have been assigned the value 1. But suppose the write invalidate is delayed, and the processor is allowed to continue during this delay. Then it is possible that both P1 and P2 have not seen the invalidations for B and A (respectively) *before* they attempt to read the values. The question now is should this behavior be allowed, and, if so, under what conditions?

The most straightforward model for memory consistency is called *sequential consistency*. Sequential consistency requires that the result of any execution be the same as though the memory accesses executed by each processor were kept in order and the accesses among different processors were arbitrarily interleaved. Sequential consistency eliminates the possibility of some nonobvious execution in the previous example because the assignments must be completed before the IF statements are initiated.

The simplest way to implement sequential consistency is to require a processor to delay the completion of any memory access until all the invalidations caused by that access are completed. Of course, it is equally effective to delay the next memory access until the previous one is completed. Remember that memory consistency involves operations among different variables: the two accesses that must be ordered are actually to different memory locations. In our example, we must delay the read of A or B ($A == 0$ or $B == 0$) until the previous write has completed ($B = 1$ or $A = 1$). Under sequential consistency, we cannot, for example, simply place the write in a write buffer and continue with the read.

Although sequential consistency presents a simple programming paradigm, it reduces potential performance, especially in a multiprocessor with a large number of processors or long interconnect delays, as we can see in the following example.

Example Suppose we have a processor where a write miss takes 50 cycles to establish ownership, 10 cycles to issue each invalidate after ownership is established, and 80 cycles for an invalidate to complete and be acknowledged once it is issued. Assuming that four other processors share a cache block, how long does a write miss stall the writing processor if the processor is sequentially consistent? Assume that the invalidates must be explicitly acknowledged before the coherence controller knows they are completed. Suppose we could continue executing after obtaining ownership for the write miss without waiting for the invalidates; how long would the write take?

Answer When we wait for invalidates, each write takes the sum of the ownership time plus the time to complete the invalidates. Because the invalidates can overlap, we need only worry about the last one, which starts $10 + 10 + 10 + 10 = 40$ cycles after ownership is established. Therefore the total time for the write is $50 + 40 + 80 = 170$ cycles. In comparison, the ownership time is only 50 cycles. With appropriate write buffer implementations, it is even possible to continue before ownership is established.

To provide better performance, researchers and architects have explored two different routes. First, they developed ambitious implementations that preserve sequential consistency but use latency-hiding techniques to reduce the penalty; we discuss these in [Section 5.7](#). Second, they developed less restrictive memory consistency models that allow for faster hardware. Such models can affect how the programmer sees the multiprocessor, so before we discuss these less restrictive models, let's look at what the programmer expects.

The Programmer's View

Although the sequential consistency model has a performance disadvantage, from the viewpoint of the programmer, it has the advantage of simplicity. The challenge

is to develop a programming model that is simple to explain and yet allows a high-performance implementation.

One such programming model that allows us to have a more efficient implementation is to assume that programs are *synchronized*. A program is synchronized if all accesses to shared data are ordered by synchronization operations. A data reference is ordered by a synchronization operation if, in every possible execution, a write of a variable by one processor and an access (either a read or a write) of that variable by another processor are separated by a pair of synchronization operations, one executed after the write by the writing processor and one executed before the access by the second processor. Cases where variables may be updated without ordering by synchronization are called *data races* because the execution outcome depends on the relative speed of the processors, and like races in hardware design, the outcome is unpredictable, which leads to another name for synchronized programs: *data-race-free*.

As a simple example, consider a variable being read and updated by two different processors. Each processor surrounds the read and update with a lock and an unlock, both to ensure mutual exclusion for the update and to ensure that the read is consistent. Clearly, every write is now separated from a read by the other processor by a pair of synchronization operations: one unlock (after the write) and one lock (before the read). Of course, if two processors are writing a variable with no intervening reads, then the writes must also be separated by synchronization operations.

It is a broadly accepted observation that most programs are synchronized. This observation is true primarily because, if the accesses were unsynchronized, the behavior of the program would likely be unpredictable because the speed of execution would determine which processor won a data race and thus affect the results of the program. Even with sequential consistency, reasoning about such programs is very difficult.

Programmers could attempt to guarantee ordering by constructing their own synchronization mechanisms, but this is extremely tricky, can lead to buggy programs, and may not be supported architecturally, meaning that they may not work in future generations of the multiprocessor. Instead, almost all programmers will choose to use synchronization libraries that are correct and optimized for the multiprocessor and the type of synchronization.

Finally, the use of standard synchronization primitives ensures that even if the architecture implements a more relaxed consistency model than sequential consistency, a synchronized program will behave as though the hardware implemented sequential consistency.

Relaxed Consistency Models: The Basics and Release Consistency

The key idea in relaxed consistency models is to allow reads and writes to complete out of order, but to use synchronization operations to enforce ordering so that a synchronized program behaves as though the processor were sequentially

consistent. There are a variety of relaxed models that are classified according to what read and write orderings they relax. We specify the orderings by a set of rules of the form $X \rightarrow Y$, meaning that operation X must complete before operation Y is done. Sequential consistency requires maintaining all four possible orderings: $R \rightarrow W$, $R \rightarrow R$, $W \rightarrow R$, and $W \rightarrow W$. The relaxed models are defined by the subset of four orderings they relax:

1. Relaxing only the $W \rightarrow R$ ordering yields a model known as *total store ordering* or *processor consistency*. Because this model retains ordering among writes, many programs that operate under sequential consistency operate under this model, without additional synchronization.
2. Relaxing both the $W \rightarrow R$ ordering and the $W \rightarrow W$ ordering yields a model known as *partial store order*.
3. Relaxing all four orderings yields a variety of models including *weak ordering*, the PowerPC consistency model, and *release consistency*, the RISC V consistency model.

By relaxing these orderings, the processor may obtain significant performance advantages, which is the reason that RISC V, ARMv8, as well as the C++ and C language standards chose release consistency as the model.

Release consistency distinguishes between synchronization operations that are used to *acquire* access to a shared variable (denoted S_A) and those that *release* an object to allow another processor to acquire access (denoted S_R). Release consistency is based on the observation that in synchronized programs, an acquire operation must precede a use of shared data, and a release operation must follow any updates to shared data and also precede the time of the next acquire. This property allows us to slightly relax the ordering by observing that a read or write that precedes an acquire need not complete before the acquire, and also that a read or write that follows a release need not wait for the release. Thus the orderings that are preserved involve only S_A and S_R , as shown in [Figure 5.23](#); as the example in [Figure 5.24](#) shows, this model imposes the fewest orders of the five models.

Release consistency provides one of the least restrictive models that is easily checkable and ensures that synchronized programs will see a sequentially consistent execution. Although most synchronization operations are either an acquire or a release (an acquire normally reads a synchronization variable and atomically updates it, and a release usually just writes it), some operations, such as a barrier, act as both an acquire and a release and cause the ordering to be equivalent to weak ordering. Although synchronization operations always ensure that previous writes have completed, we may want to guarantee that writes are completed without an identified synchronization operation. In such cases, an explicit instruction, called FENCE in RISC V, is used to ensure that all previous instructions in that thread have completed, including completion of all memory writes and associated invalidates. For more information about the complexities, implementation issues, and

Model	Used in	Ordinary orderings	Synchronization orderings
Sequential consistency	Most machines as an optional mode	$R \rightarrow R, R \rightarrow W, W \rightarrow R, W \rightarrow W$	$S \rightarrow W, S \rightarrow R, R \rightarrow S, W \rightarrow S, S \rightarrow S$
Total store order or processor consistency	IBMS/370, DEC VAX, SPARC	$R \rightarrow R, R \rightarrow W, W \rightarrow W$	$S \rightarrow W, S \rightarrow R, R \rightarrow S, W \rightarrow S, S \rightarrow S$
Partial store order	SPARC	$R \rightarrow R, R \rightarrow W$	$S \rightarrow W, S \rightarrow R, R \rightarrow S, W \rightarrow S, S \rightarrow S$
Weak ordering	PowerPC		$S \rightarrow W, S \rightarrow R, R \rightarrow S, W \rightarrow S, S \rightarrow S$
Release consistency	MIPS, RISC V, Armv8, C, and C++ specifications		$S_A \rightarrow W, S_A \rightarrow R, R \rightarrow S_R, W \rightarrow S_R, S_A \rightarrow S_A, S_A \rightarrow S_R, S_R \rightarrow S_A, S_R \rightarrow S_R$

Figure 5.23 The orderings imposed by various consistency models are shown for both ordinary accesses and synchronization accesses. The models grow from most restrictive (sequential consistency) to least restrictive (release consistency), allowing increased flexibility in the implementation. The weaker models rely on fences created by synchronization operations, as opposed to an implicit fence at every memory operation. S_A and S_R stand for acquire and release operations, respectively, and are needed to define release consistency. If we were to use the notation S_A and S_R for each S consistently, each ordering with one S would become two orderings (e.g., $S \rightarrow W$ becomes $S_A \rightarrow W$, $S_R \rightarrow W$), and each $S \rightarrow S$ would become the four orderings shown in the last line of the bottom-right table entry.

Figure 5.24 These examples of the five consistency models discussed in this section show the reduction in the number of orders imposed as the models become more relaxed. Only the minimum orders are shown with arrows. Orders implied by transitivity, such as the write of C before the release of S in the sequential consistency model or the acquire before the release in weak ordering or release consistency, are not shown.

performance potential from relaxed models, we highly recommend the excellent tutorial by [Adve and Gharachorloo \(1996\)](#).

5.7

Cross-Cutting Issues

Because multiprocessors redefine many system characteristics (e.g., performance assessment, memory latency, and the importance of scalability), they introduce interesting design problems that cut across the spectrum, affecting both hardware and software. In this section, we give several examples related to the issue of memory consistency. We then examine the performance gained when multithreading is added to multiprocessing.

Compiler Optimization and the Consistency Model

Another reason for defining a model for memory consistency is to specify the range of legal compiler optimizations that can be performed on shared data. In explicitly parallel programs, unless the synchronization points are clearly defined and the programs are synchronized, the compiler cannot interchange a read and a write of two different shared data items because such transformations might affect the semantics of the program. This restriction prevents even relatively simple optimizations, such as register allocation of shared data, because such a process usually interchanges reads and writes. In implicitly parallelized programs—for example, those written in High Performance Fortran (HPF)—programs must be synchronized and the synchronization points are known, so this issue does not arise. Whether compilers can get significant advantage from more relaxed consistency models remains an open question, both from a research viewpoint and from a practical viewpoint, where the lack of uniform models is likely to retard progress on deploying compilers.

Using Speculation to Hide Latency in Strict Consistency Models

As we saw in [Chapter 3](#), speculation can be used to hide memory latency. It can also be used to hide latency arising from a strict consistency model, giving much of the benefit of a relaxed memory model. The key idea is for the processor to use dynamic scheduling to reorder memory references, letting them possibly execute out of order. Executing the memory references out of order may generate violations of sequential consistency, which might affect the execution of the program. This possibility is avoided by using the delayed commit feature of a speculative processor. Assume the coherency protocol is based on invalidation. If the processor receives an invalidation for a memory reference before the memory reference is committed, the processor uses speculation recovery to back out of the computation and restart with the memory reference whose address was invalidated.

If the reordering of memory requests by the processor yields an execution order that could result in an outcome that differs from what would have been seen under

sequential consistency, the processor will redo the execution. The key to using this approach is that the processor need only guarantee that the result would be the same as if all accesses were completed in order, and it can achieve this by detecting when the results might differ. The approach is attractive because the speculative restart will rarely be triggered. It will be triggered only when there are unsynchronized accesses that actually cause a race (Gharachorloo et al., 1992).

Hill (1998) advocated the combination of sequential or processor consistency together with speculative execution as the consistency model of choice. His argument has three parts. First, an aggressive implementation of either sequential consistency or processor consistency will gain most of the advantage of a more relaxed model. Second, such an implementation adds very little to the implementation cost of a speculative processor. Third, such an approach allows the programmer to reason using the simpler programming models of either sequential or processor consistency. The MIPS R10000 design team had this insight in the mid-1990s and used the R10000's out-of-order capability to support this type of aggressive implementation of sequential consistency.

One open question is how successful compiler technology will be in optimizing memory references to shared variables. The state of optimization technology and the fact that shared data are often accessed via pointers or array indexing have limited the use of such optimizations. If this technology were to become available and lead to significant performance advantages, compiler writers would want to be able to take advantage of a more relaxed programming model. This possibility and the desire to keep the future as flexible as possible led the RISC V designers to opt for release consistency, after a long series of debates.

Inclusion and Its Implementation

All multiprocessors use multilevel cache hierarchies to reduce both the demand on the global interconnect and the latency of cache misses. If the cache also provides *multilevel inclusion*—every level of cache hierarchy is a subset of the level farther away from the processor—then we can use the multilevel structure to reduce the contention between coherence traffic and processor traffic that occurs when snoops and processor cache accesses must contend for the cache. Many multiprocessors with multilevel caches enforce the inclusion property, although recent multiprocessors with smaller L1 caches and different block sizes have sometimes chosen not to enforce inclusion. This restriction is also called the *subset property* because each cache is a subset of the cache below it in the hierarchy.

At first glance, preserving the multilevel inclusion property seems trivial. Consider a two-level example: Any miss in L1 either hits in L2 or generates a miss in L2, causing it to be brought into both L1 and L2. Likewise, any invalidate that hits in L2 must be sent to L1, where it will cause the block to be invalidated if it exists.

The catch is what happens when the block sizes of L1 and L2 are different. Choosing different block sizes is quite reasonable, since L2 will be much larger and have a much longer latency component in its miss penalty, and thus will want

to use a larger block size. What happens to our “automatic” enforcement of inclusion when the block sizes differ? A block in L2 represents multiple blocks in L1, and a miss in L2 causes the replacement of data that is equivalent to multiple L1 blocks. For example, if the block size of L2 is four times that of L1, then a miss in L2 will replace the equivalent of four L1 blocks. Let’s consider a detailed example.

Example Assume that L2 has a block size four times that of L1. Show how a miss for an address that causes a replacement in L1 and L2 can lead to violation of the inclusion property.

Answer Assume that L1 and L2 are direct-mapped and that the block size of L1 is b bytes and the block size of L2 is $4b$ bytes. Suppose L1 contains two blocks with starting addresses x and $x+b$ and that $x \bmod 4b = 0$, meaning that x also is the starting address of a block in L2; then that single block in L2 contains the L1 blocks x , $x+b$, $x+2b$, and $x+3b$. Suppose the processor generates a reference to block y that maps to the block containing x in both caches and thus misses. Because L2 missed, it fetches $4b$ bytes and replaces the block containing x , $x+b$, $x+2b$, and $x+3b$, while L1 takes b bytes and replaces the block containing x . Because L1 still contains $x+b$, but L2 does not, the inclusion property no longer holds.

To maintain inclusion with multiple block sizes, we must probe the higher levels of the hierarchy when a replacement is done at the lower level to ensure that any words replaced in the lower level are invalidated in the higher-level caches; different levels of associativity create the same sort of problems. [Baer and Wang \(1988\)](#) described the advantages and challenges of inclusion in detail, and in 2017 most designers have opted to implement inclusion, often by settling on one block size for all levels in the cache. For example, the Intel i7 uses inclusion for L3, meaning that L3 always includes the contents of all of L2 and L1. This decision allows the i7 to implement a straightforward directory scheme at L3 and to minimize the interference from snooping on L1 and L2 to those circumstances where the directory indicates that L1 or L2 have a cached copy. The AMD Opteron, in contrast, makes L2 inclusive of L1 but has no such restriction for L3. It uses a snooping protocol, but only needs to snoop at L2 unless there is a hit, in which case a snoop is sent to L1.

Performance Gains From Multiprocessing and Multithreading

In this section, we briefly look at a study of the effectiveness of using multithreading on a multicore processor, the IBM Power5; we will return to this topic in the next section, when we examine the performance of the Intel i7. The IBM Power5 is a dual-core that supports simultaneous multithreading (SMT); its basic architecture is very similar to the more recent Power8 (which we examine in the next section), but it has only two cores per processor.

Figure 5.25 A comparison of SMT and single-thread (ST) performance on the 8-processor IBM eServer p5 575 using SPECfpRate (top half) and SPECintRate (bottom half) as benchmarks. Note that the x-axis starts at a speedup of 0.9, a performance loss. Only one processor in each Power5 core is active, which should slightly improve the results from SMT by decreasing destructive interference in the memory system. The SMT results are obtained by creating 16 user threads, whereas the ST results use only eight threads; with only one thread per processor, the Power5 is switched to single-threaded mode by the OS. These results were collected by John McCalpin at IBM. As we can see from the data, the standard deviation of the results for the SPECfpRate is higher than for SPECintRate (0.13 versus 0.07), indicating that the SMT improvement for FP programs is likely to vary widely.

To examine the performance of multithreading in a multiprocessor, measurements were made on an IBM system with eight Power5 processors, using only one core on each processor. Figure 5.25 shows the speedup for an 8-processor Power5 multiprocessor, with and without SMT, for the SPECRate2000 benchmarks, as described in the caption. On average, the SPECintRate is 1.23 times faster, and the SPECfpRate is 1.16 times faster. Note that a few floating-point benchmarks experience a slight decrease in performance in SMT mode, with the maximum

reduction in speedup being 0.93. Although one might expect that SMT would do a better job of hiding the higher miss rates of the SPEC FP benchmarks, it appears that limits in the memory system are encountered when running in SMT mode on such benchmarks.

5.8

Putting It All Together: Multicore Processors and Their Performance

For roughly 10 years, multicore has been the primary focus for scaling performance, although the implementations vary widely, as does their support for larger multichip multiprocessors. In this section, we examine the design of three different multicores, the support they provide for larger multiprocessors, and some performance characteristics, before doing a broader evaluation of small to large multiprocessor Xeon systems, and concluding with a detailed evaluation of the multicore i7 920, a predecessor of the i7 6700.

Performance of Multicore-Based Multiprocessors on a Multiprogrammed Workload

Figure 5.26 shows the key characteristics of three multicore processors designed for server applications and available in 2015 through 2017. The Intel Xeon E7 is based on the same basic design as the i7, but it has more cores, a slightly slower clock rate (power is the limitation), and a larger L3 cache. The Power8 is the newest in the IBM Power series and features more cores and bigger caches. The Fujitsu SPARC64 X+ is the newest SPARC server chip; unlike the T-series mentioned in Chapter 3, it uses SMT. Because these processors are configured for multicore and multiprocessor servers, they are available as a family, varying processor count, cache size, and so on, as the figure shows.

These three systems show a range of techniques both for connecting the on-chip cores and for connecting multiple processor chips. First, let's look at how the cores are connected within a chip. The SPARC64 X+ is the simplest: it shares a single L2 cache, which is 24-way set associative, among the 16 cores. There are four separate DIMM channels to attach memory accessible with a 16×4 switch between the cores and the channels.

Figure 5.27 shows how the Power8 and Xeon E7 chips are organized. Each core in the Power8 has an 8 MiB bank of L3 directly connected; other banks are accessed via the interconnection network, which has 8 separate buses. Thus the Power8 is a true NUCA (*Nonuniform Cache Architecture*), because the access time to the attached bank of L3 will be much faster than accessing another L3. Each Power8 chip has a set of links that can be used to build a large multiprocessor using an organization we will see shortly. The memory links are connected to a special memory controller that includes an L4 and interfaces directly with DIMMs.

Part B of Figure 5.27, shows how the Xeon E7 processor chip is organized when there are 18 or more cores (20 cores are shown in this figure). Three rings

Feature	IBM Power8	Intel Xeon E7	Fujitsu SPARC64 X+
Cores/chip	4, 6, 8, 10, 12	4, 8, 10, 12, 22, 24	16
Multithreading	SMT	SMT	SMT
Threads/core	8	2	2
Clock rate	3.1–3.8 GHz	2.1–3.2 GHz	3.5 GHz
L1 I cache	32 KB per core	32 KB per core	64 KB per core
L1 D cache	64 KB per core	32 KB per core	64 KB per core
L2 cache	512 KB per core	256 KB per core	24 MiB shared
L3 cache	L3: 32–96 MiB; 8 MiB per core (using eDRAM); shared with nonuniform access time	10–60 MiB @ 2.5 MiB per core; shared, with larger core counts	None
Inclusion	Yes, L3 superset	Yes, L3 superset	Yes
Multicore coherence protocol	Extended MESI with behavioral and locality hints (13-states)	MESIF: an extended form of MESI allowing direct transfers of clean blocks	MOESI
Multichip coherence implementation	Hybrid strategy with snooping and directory	Hybrid strategy with snooping and directory	Hybrid strategy with snooping and directory
Multiprocessor interconnect support	Can connect up to 16 processor chips with 1 or 2 hops to reach any processor	Up to 8 processor chips directly via Quickpath; larger system and directory support with additional logic	Crossbar interconnect chip, supports up to 64 processors; includes directory support
Processor chip range	1–16	2–32	1–64
Core count range	4–192	12–576	8–1024

Figure 5.26 Summary of the characteristics of three recent high-end multicore processors (2015–2017 releases) designed for servers. The table shows the range of processor counts, clock rates, and cache sizes within each processor family. The Power8 L3 is a NUCA (Nonuniform Cache Access) design, and it also supports off-chip L4 of up to 128 MiB using EDRAM. A 32-core Xeon has recently been announced, but no system shipments have occurred. The Fujitsu SPARC64 is also available as an 8-core design, which is normally configured as a single processor system. The last row shows the range of configured systems with published performance data (such as SPECintRate) with both processor chip counts and total core counts. The Xeon systems include multiprocessors that extend the basic interconnect with additional logic; for example, using the standard Quickpath interconnect limits the processor count to 8 and the largest system to $8 \times 24 = 192$ cores, but SGI extends the interconnect (and coherence mechanisms) with extra logic to offer a 32 processor system using 18-core processor chips for a total size of 576 cores. Newer releases of these processors increased clock rates (significantly in the Power8 case, less so in others) and core counts (significantly in the case of Xeon).

connect the cores and the L3 cache banks, and each core and each bank of L3 is connected to two rings. Thus any cache bank or any core is accessible from any other core by choosing the right ring. Therefore, within the chip, the E7 has uniform access time. In practice, however, the E7 is normally operated as a NUMA architecture by logically associating half the cores with each memory channel; this

increases the probability that a desired memory page is open on a given access. The E7 provides 3 QuickPath Interconnect (QPI) links for connecting multiple E7s.

Multiprocessors consisting of these multicores use a variety of different interconnection strategies, as [Figure 5.28](#) shows. The Power8 design provides support for connecting 16 Power8 chips for a total of 192 cores. The intragroup links provide higher bandwidth interconnect among a completely connected module of 4 processor chips. The intergroup links are used to connect each processor chip to the 3 other modules. Thus each processor is two hops from any other, and the memory access time is determined by whether an address resides in local memory, cluster memory, or intercluster memory (actually the latter can have two different values, but the difference is swamped by the intercluster time).

The Xeon E7 uses QPI to interconnect multiple multicore chips. In a 4-chip, multiprocessor, which with the latest announced Xeon could have 128 cores, the three QPI links on each processor are connected to three neighbors, yielding a 4-chip fully connected multiprocessor. Because memory is directly connected to each E7 multicore, even this 4-chip arrangement has nonuniform memory access time (local versus remote). [Figure 5.28](#) shows how 8 E7 processors can be connected; like the Power8, this leads to a situation where every processor is one or two hops from every other processor. There are a number of Xeon-based multiprocessor servers that have more than 8 processor chips. In such designs, the typical organization is to connect 4 processor chips together in a square, as a module, with each processor connecting to two neighbors. The third QPI in each chip is connected to a crossbar switch. Very large systems can be created in this fashion. Memory accesses can then occur at four locations with different timings: local to the processor, an immediate neighbor, the neighbor in the cluster that is two hops away, and through the crossbar. Other organizations are possible and require less than a full crossbar in return for more hops to get to remote memory.

The SPARC64 X+ also uses a 4-processor module, but each processor has three connections to its immediate neighbors plus two (or three in the largest configuration) connections to a crossbar. In the largest configuration, 64 processor chips can be connected to two crossbar switches, for a total of 1024 cores. Memory access is NUMA (local, within a module, and through the crossbar), and coherency is directory-based.

Performance of Multicore-Based Multiprocessors on a Multiprogrammed Workload

First, we compare the performance scalability of these three multicore processors using SPECintRate, considering configurations up to 64 cores. [Figure 5.29](#) shows how the performance scales relative to the performance of the smallest configuration, which varies between 4 and 16 cores. In the plot, the smallest configuration is assumed to have perfect speedup (i.e., 8 for 8 cores, 12 for 12 cores, etc.). This figure does *not* show performance among these different processors. Indeed such performance varies significantly: in the 4-core configuration, the IBM Power8 is

Figure 5.28 The system architecture for three multiprocessors built from multicore chips.

Figure 5.29 The performance scaling on the SPECintRate benchmarks for four multicore processors as the number of cores is increased to 64. Performance for each processor is plotted relative to the smallest configuration and assuming that configuration had perfect speedup. Although this chart shows how a given multiprocessor scales with additional cores, it does not supply any data about performance among processors. There are differences in the clock rates, even within a given processor family. These are generally swamped by the core scaling effects, except for the Power8 that shows a clock range spread of $1.5\times$ from the smallest configuration to the 64 core configuration.

1.5 times as fast as the SPARC64 X+ on a per core basis! Instead [Figure 5.29](#) shows how the performance scales for each processor family as additional cores are added.

Two of the three processors show diminishing returns as they scale to 64 cores. The Xeon systems appear to show the most degradation at 56 and 64 cores. This may be largely due to having more cores share a smaller L3. For example, the 40-core system uses 4 chips, each with 60 MiB of L3, yielding 6 MiB of L3 per core. The 56-core and 64-core systems also use 4 chips but have 35 or 45 MiB of L3 per chip, or 2.5–2.8 MiB per core. It is likely that the resulting larger L3 miss rates lead to the reduction in speedup for the 56-core and 64-core systems.

The IBM Power8 results are also unusual, appearing to show significant super-linear speedup. This effect, however, is due largely to differences in the clock rates, which are much larger across the Power8 processors than for the other processors

Figure 5.30 The scaling of relative performance for multiprocessor multicore. As before, performance is shown relative to the smallest available system. The Xeon result at 80 cores is the same L3 effect that showed up for smaller configurations. All systems larger than 80 cores have between 2.5 and 3.8 MiB of L3 per core, and the 80-core, or smaller, systems have 6 MiB per core.

in this figure. In particular, the 64-core configuration has the highest clock rate (4.4 GHz), whereas the 4-core configuration has a 3.0 GHz clock. If we normalize the relative speedup for the 64-core system based on the clock rate differential with the 4-core system, the effective speedup is 57 rather than 84. Therefore, while the Power8 system scales well, and perhaps the best among these processors, it is not miraculous.

Figure 5.30 shows scaling for these three systems at configurations above 64 processors. Once again, the clock rate differential explains the Power8 results; the clock-rate equivalent scaled speedup with 192 processors is 167, versus 223, when not accounting for clock rate differences. Even at 167, the Power8 scaling is somewhat better than that on the SPARC64 X+ or Xeon systems. Surprisingly, although there are some effects on speedup in going from the smallest system to 64 cores, they do not seem to get dramatically worse at these larger configurations. The nature of the workload, which is highly parallel and user-CPU-intensive, and the overheads paid in going to 64 cores probably lead to this result.

Scalability in an Xeon MP With Different Workloads

In this section, we focus on the scalability of the Xeon E7 multiprocessors on three different workloads: a Java-based commercially oriented workload, a virtual machine workload, and a scientific parallel processing workload, all from the SPEC benchmarking organization, as described next.

- SPECjbb2015: Models a supermarket IT system that handles a mix of point-of-sale requests, online purchases, and data-mining operations. The performance metric is throughput-oriented, and we use the maximum performance measurement on the server side running multiple Java virtual machines.
- SPECVirt2013: Models a collection of virtual machines running independent mixes of other SPEC benchmarks, including CPU benchmarks, web servers, and mail servers. The system must meet a quality of service guarantee for each virtual machine.
- SPECOMP2012: A collection of 14 scientific and engineering programs written with the OpenMP standard for shared-memory parallel processing. The codes are written in Fortran, C, and C++ and range from fluid dynamics to molecular modeling to image manipulation.

As with the previous results, [Figure 5.31](#) shows performance assuming linear speedup on the smallest configuration, which for these benchmarks varies from 48 cores to 72 cores, and plotting performance relative to the that smallest configuration. The SPECjbb2015 and SPECVirt2013 include significant systems software, including the Java VM software and the VM hypervisor. Other than the system software, the interaction among the processes is very small. In contrast, SPECOMP2012 is a true parallel code with multiple user processes sharing data and collaborating in the computation.

Let's begin by examining SPECjbb2015. It obtains speedup efficiency (speedup/processor ratio) of between 78% and 95%, showing good speedup, even in the largest configuration. SPECVirt2013 does even better (for the range of system measured), obtaining almost linear speedup at 192 cores. Both SPECjbb2015 and SPECVirt2013 are benchmarks that scale up the application size (as in the TPC benchmarks discussed in [Chapter 1](#)) with larger systems so that the effects of Amdahl's Law and interprocess communication are minor.

Finally, let's turn to SPECOMP2012, the most compute-intensive of these benchmarks and the one that truly involves parallel processing. The major trend visible here is a steady loss of efficiency as we scale from 30 to 576 cores so that by 576 cores, the system exhibits only half the efficiency it showed at 30 cores. This reduction leads to a relative speedup of 284, assuming that the 30-core speedup is 30. These are probably Amdahl's Law effects resulting from limited parallelism as well as synchronization and communication overheads. Unlike

Figure 5.31 Scaling of performance on a range of Xeon E7 systems showing performance relative to the smallest benchmark configuration, and assuming that configuration gets perfect speedup (e.g., the smallest SPEWCOMP configuration is 30 cores and we assume a performance of 30 for that system). Only relative performance can be assessed from this data, and comparisons across the benchmarks have no relevance. Note the difference in the scale of the vertical and horizontal axes.

the SPECjbb2015 and SPECVirt2013, these benchmarks are not scaled for larger systems.

Performance and Energy Efficiency of the Intel i7 920 Multicore

In this section, we closely examine the performance of the i7 920, a predecessor of the 6700, on the same two groups of benchmarks we considered in [Chapter 3](#): the parallel Java benchmarks and the parallel PARSEC benchmarks (described in detail in [Figure 3.32](#) on page 247). Although this study uses the older i7 920, it remains, by far, the most comprehensive study of energy efficiency in multicore processors and the effects of multicore combined with SMT. The fact that the i7 920 and 6700 are similar indicates that the basic insights should also apply to the 6700.

First, we look at the multicore performance and scaling versus a single-core without the use of SMT. Then we combine both the multicore and SMT capability. All the data in this section, like that in the earlier i7 SMT evaluation (Chapter 3) come from [Esmaeilzadeh et al. \(2011\)](#). The dataset is the same as that used earlier (see [Figure 3.32](#) on page 247), except that the Java benchmarks *tradebeans* and *pjbb2005* are removed (leaving only the five scalable Java benchmarks); *tradebeans* and *pjbb2005* never achieve speedup above 1.55 even with four cores and a total of eight threads, and thus are not appropriate for evaluating more cores.

[Figure 5.32](#) plots both the speedup and energy efficiency of the Java and PARSEC benchmarks without the use of SMT. Energy efficiency is computed by the ratio: energy consumed by the single-core run divided by the energy consumed by the two- or four-core run (i.e., efficiency is the inverse of energy consumed). Higher energy efficiency means that the processor consumes less energy for the same computation, with a value of 1.0 being the break-even

Figure 5.32 This chart shows the speedup and energy efficiency for two- and four-core executions of the parallel Java and PARSEC workloads without SMT. These data were collected by [Esmaeilzadeh et al. \(2011\)](#) using the same setup as described in [Chapter 3](#). Turbo Boost is turned off. The speedup and energy efficiency are summarized using harmonic mean, implying a workload where the total time spent running each benchmark on 2 cores is equivalent.

point. The unused cores in all cases were in deep sleep mode, which minimized their power consumption by essentially turning them off. In comparing the data for the single-core and multicore benchmarks, it is important to remember that the full energy cost of the L3 cache and memory interface is paid in the single-core (as well as the multicore) case. This fact increases the likelihood that energy consumption will improve for applications that scale reasonably well. Harmonic mean is used to summarize results with the implication described in the caption.

As the figure shows, the PARSEC benchmarks get better speedup than the Java benchmarks, achieving 76% speedup efficiency (i.e., actual speedup divided by processor count) on four cores, whereas the Java benchmarks achieve 67% speedup efficiency on four cores. Although this observation is clear from the data, analyzing why this difference exists is difficult. It is quite possible that Amdahl's Law effects have reduced the speedup for the Java workload, which includes some typically serial parts, such as the garbage collector. In addition, interaction between the processor architecture and the application, which affects issues such as the cost of synchronization or communication, may also play a role. In particular, well-parallelized applications, such as those in PARSEC, sometimes benefit from an advantageous ratio between computation and communication, which reduces the dependence on communications costs (see Appendix I).

These differences in speedup translate to differences in energy efficiency. For example, the PARSEC benchmarks actually slightly improve energy efficiency over the single-core version; this result may be significantly affected by the fact that the L3 cache is more effectively used in the multicore runs than in the single-core case and the energy cost is identical in both cases. Thus, for the PARSEC benchmarks, the multicore approach achieves what designers hoped for when they switched from an ILP-focused design to a multicore design; namely, it scales performance as fast or faster than scaling power, resulting in constant or even improved energy efficiency. In the Java case, we see that neither the two- nor four-core runs break even in energy efficiency because of the lower speedup levels of the Java workload (although Java energy efficiency for the 2p run is the same as for PARSEC). The energy efficiency in the four-core Java case is reasonably high (0.94). It is likely that an ILP-centric processor would need *even more* power to achieve a comparable speedup on either the PARSEC or Java workload. Thus the TLP-centric approach is also certainly better than the ILP-centric approach for improving performance for these applications. As we will see in [Section 5.10](#), there are reasons to be pessimistic about simple, efficient, long-term scaling of multicore.

Putting Multicore and SMT Together

Finally, we consider the combination of multicore and multithreading by measuring the two benchmark sets for two to four processors and one to two threads (a total of four data points and up to eight threads). [Figure 5.33](#) shows the speedup

Figure 5.33 This chart shows the speedup for two- and four-core executions of the parallel Java and PARSEC workloads both with and without SMT. Remember that the preceding results vary in the number of threads from two to eight and reflect both architectural effects and application characteristics. Harmonic mean is used to summarize results, as discussed in the [Figure 5.32](#) caption.

and energy efficiency obtained on the Intel i7 when the processor count is two or four and SMT is or is not employed, using harmonic mean to summarize the two benchmarks sets. Clearly, SMT can add to performance when there is sufficient thread-level parallelism available even in the multicore situation. For example, in the four-core, no-SMT case, the speedup efficiencies were 67% and 76% for Java and PARSEC, respectively. With SMT on four cores, those ratios are an astonishing 83% and 97%.

Energy efficiency presents a slightly different picture. In the case of PARSEC, speedup is essentially linear for the four-core SMT case (eight threads), and power scales more slowly, resulting in an energy efficiency of 1.1 for that case. The Java situation is more complex; energy efficiency peaks for the two-core SMT (four-thread) run at 0.97 and drops to 0.89 in the four-core SMT (eight-thread) run. It seems highly likely that the Java benchmarks are encountering Amdahl's Law effects when more than four threads are deployed. As some architects have observed, multicore does shift more responsibility for performance (and thus energy efficiency) to the programmer, and the results for the Java workload certainly bear this out.

5.9

Fallacies and Pitfalls

Given the lack of maturity in our understanding of parallel computing, there are many hidden pitfalls that will be uncovered either by careful designers or by unfortunate ones. Given the large amount of hype that has surrounded multiprocessors over the years, common fallacies abound. We have included a selection of them.

Pitfall *Measuring performance of multiprocessors by linear speedup versus execution time.*

Graphs like those in [Figures 5.32 and 5.33](#), which plot performance versus number of processors, showing linear speedup, a plateau, and then a falling off, have long been used to judge the success of parallel processors. Although speedup is one facet of a parallel program, it is not a direct measure of performance. The first issue is the power of the processors being scaled: a program that linearly improves performance to equal 100 Intel Atom processors (the low-end processor used for netbooks) may be slower than the version run on an 8-core Xeon. Be especially careful of floating-point-intensive programs; processing elements without hardware assist may scale wonderfully but have poor collective performance.

Comparing execution times is fair only if you are comparing the best algorithms on each computer. Comparing the identical code on two computers may seem fair, but it is not; the parallel program may be slower on a uniprocessor than on a sequential version. Developing a parallel program will sometimes lead to algorithmic improvements, so comparing the previously best-known sequential program with the parallel code—which seems fair—will not compare equivalent algorithms. To reflect this issue, the terms *relative speedup* (same program) and *true speedup* (best program) are sometimes used.

Results that suggest *superlinear* performance, when a program on n processors is more than n times faster than the equivalent uniprocessor, may indicate that the comparison is unfair, although there are instances where “real” superlinear speedups have been encountered. For example, some scientific applications regularly achieve superlinear speedup for small increases in processor count (2 or 4 to 8 or 16). These results usually arise because critical data structures that do not fit into the aggregate caches of a multiprocessor with 2 or 4 processors fit into the aggregate cache of a multiprocessor with 8 or 16 processors. As we saw in the previous section, other differences (such as high clock rate) may appear to yield superlinear speedups when comparing slightly different systems.

In summary, comparing performance by comparing speedups is at best tricky and at worst misleading. Comparing the speedups for two different multiprocessors does not necessarily tell us anything about the relative performance of the multiprocessors, as we also saw in the previous section. Even comparing two different algorithms on the same multiprocessor is tricky because we must use true speedup, rather than relative speedup, to obtain a valid comparison.

Fallacy *Amdahl's Law doesn't apply to parallel computers.*

In 1987 the head of a research organization claimed that Amdahl's Law (see [Section 1.9](#)) had been broken by an MIMD multiprocessor. This statement hardly

meant, however, that the law has been overturned for parallel computers; the neglected portion of the program will still limit performance. To understand the basis of the media reports, let's see what [Amdahl \(1967\)](#) originally said:

A fairly obvious conclusion which can be drawn at this point is that the effort expended on achieving high parallel processing rates is wasted unless it is accompanied by achievements in sequential processing rates of very nearly the same magnitude. [p. 483]

One interpretation of the law was that, because portions of every program must be sequential, there is a limit to the useful economic number of processors—say, 100. By showing linear speedup with 1000 processors, this interpretation of Amdahl's Law was disproved.

The basis for the statement that Amdahl's Law had been “overcome” was the use of *scaled speedup*, also called *weak scaling*. The researchers scaled the benchmark to have a dataset size that was 1000 times larger and compared the uniprocessor and parallel execution times of the scaled benchmark. For this particular algorithm, the sequential portion of the program was constant independent of the size of the input, and the rest was fully parallel—thus, linear speedup with 1000 processors. Because the running time grew faster than linear, the program actually ran longer after scaling, even with 1000 processors.

Speedup that assumes scaling of the input is not the same as true speedup, and reporting it as if it were is misleading. Because parallel benchmarks are often run on different-sized multiprocessors, it is important to specify what type of application scaling is permissible and how that scaling should be done. Although simply scaling the data size with processor count is rarely appropriate, assuming a fixed problem size for a much larger processor count (called *strong scaling*) is often inappropriate, as well, because it is likely that users given a much larger multiprocessor would opt to run a larger or more detailed version of an application. See Appendix I for more discussion on this important topic.

Fallacy *Linear speedups are needed to make multiprocessors cost-effective.*

It is widely recognized that one of the major benefits of parallel computing is to offer a “shorter time to solution” than the fastest uniprocessor. Many people, however, also hold the view that parallel processors cannot be as cost-effective as uniprocessors unless they can achieve perfect linear speedup. This argument says that, because the cost of the multiprocessor is a linear function of the number of processors, anything less than linear speedup means that the performance/cost ratio decreases, making a parallel processor less cost-effective than using a uniprocessor.

The problem with this argument is that cost is not only a function of processor count but also depends on memory, I/O, and the overhead of the system (box, power supply, interconnect, etc.). It also makes less sense in the multicore era, when there are multiple processors per chip.

The effect of including memory in the system cost was pointed out by [Wood and Hill \(1995\)](#). We use an example based on more recent data using TPC-C and SPECRate benchmarks, but the argument could also be made with a parallel scientific application workload, which would likely make the case even stronger.

Figure 5.34 Speedup for three benchmarks on an IBM eServer p5 multiprocessor when configured with 4, 8, 16, 32, and 64 processors. The *dashed* line shows linear speedup.

Figure 5.34 shows the speedup for TPC-C, SPECintRate, and SPECfpRate on an IBM eServer p5 multiprocessor configured with 4–64 processors. The figure shows that only TPC-C achieves better than linear speedup. For SPECintRate and SPECfpRate, speedup is less than linear, but so is the cost, because unlike TPC-C, the amount of main memory and disk required both scale less than linearly.

As Figure 5.35 shows, larger processor counts can actually be more cost-effective than the 4-processor configuration. In comparing the cost-performance of two computers, we must be sure to include accurate assessments of both total system cost and what performance is achievable. For many applications with larger memory demands, such a comparison can dramatically increase the attractiveness of using a multiprocessor.

Pitfall *Not developing the software to take advantage of, or optimize for, a multiprocessor architecture.*

There is a long history of software lagging behind on multiprocessors, probably because the software problems are much harder. We give one example to show the subtlety of the issues, but there are many examples we could choose from.

One frequently encountered problem occurs when software designed for a uniprocessor is adapted to a multiprocessor environment. For example, the SGI

Figure 5.35 The performance/cost for IBM eServer p5 multiprocessors with 4–64 processors is shown relative to the 4-processor configuration. Any measurement above 1.0 indicates that the configuration is more cost-effective than the 4-processor system. The 8-processor configurations show an advantage for all three benchmarks, whereas two of the three benchmarks show a cost-performance advantage in the 16- and 32-processor configurations. For TPC-C, the configurations are those used in the official runs, which means that disk and memory scale nearly linearly with processor count, and a 64-processor machine is approximately twice as expensive as a 32-processor version. In contrast, the disk and memory are scaled more slowly (although still faster than necessary to achieve the best SPECRate at 64 processors). In particular, the disk configurations go from one drive for the 4-processor version to four drives (140 GB) for the 64-processor version. Memory is scaled from 8 GiB for the 4-processor system to 20 GiB for the 64-processor system.

operating system in 2000 originally protected the page table data structure with a single lock, assuming that page allocation was infrequent. In a uniprocessor, this does not represent a performance problem. In a multiprocessor, it can become a major performance bottleneck for some programs.

Consider a program that uses a large number of pages that are initialized at startup, which UNIX does for statically allocated pages. Suppose the program is parallelized so that multiple processes allocate the pages. Because page allocation requires the use of the page table data structure, which is locked whenever it is in use, even an OS kernel that allows multiple threads in the OS will be serialized if the processes all try to allocate their pages at once (which is exactly what we might expect at initialization time).

This page table serialization eliminates parallelism in initialization and has significant impact on overall parallel performance. This performance bottleneck persists even under multiprogramming. For example, suppose we split the parallel program apart into separate processes and run them, one process per processor, so that there is no sharing between the processes. (This is exactly what one user did, because he reasonably believed that the performance problem was due to unintended sharing or interference in his application.) Unfortunately, the lock still serializes all the processes, so even the multiprogramming performance is poor. This pitfall indicates the kind of subtle but significant performance bugs that can arise when software runs on multiprocessors. Like many other key software components, the OS algorithms and data structures must be rethought in a multiprocessor context. Placing locks on smaller portions of the page table effectively eliminates the problem. Similar problems exist in memory structures, which increases the coherence traffic in cases where no sharing is actually occurring.

As multicore became the dominant theme in everything from desktops to servers, the lack of an adequate investment in parallel software became apparent. Given the lack of focus, it will likely be many years before the software systems we use adequately exploit the growing numbers of cores.

5.10

The Future of Multicore Scaling

For more than 30 years, researchers and designers have predicted the end of uniprocessors and their dominance by multiprocessors. Until the early years of this century, this prediction was constantly proven wrong. As we saw in [Chapter 3](#), the costs of trying to find and exploit more ILP became prohibitive in efficiency (both in silicon area and in power). Of course, multicore does not magically solve the power problem because it clearly increases both the transistor count and the active number of transistors switching, which are the two dominant contributions to power. As we will see in this section, energy issues are likely to limit multicore scaling more severely than previously thought.

ILP scaling failed because of both limitations in the ILP available and the efficiency of exploiting that ILP. Similarly, a combination of two factors means that simply scaling performance by adding cores is unlikely to be broadly successful. This combination arises from the challenges posed by Amdahl's Law, which assesses the efficiency of exploiting parallelism, and the end of Dennard's Scaling, which dictates the energy required for a multicore processor.

To understand these factors, we take a simple model of both technology scaling (based on an extensive and highly detailed analysis in Esmaeilzadeh et al. (2012)). Let's start by reviewing energy consumption and power in CMOS. Recall from [Chapter 1](#) that the energy to switch a transistor is given as

$$\text{Energy} \propto \text{Capacitive load} \times \text{Voltage}^2$$

CMOS scaling is limited primarily by thermal power, which is a combination of static leakage power and dynamic power, which tends to dominate. Power is given by

Device count scaling (since a transistor is 1/4 the size)	4
Frequency scaling (based on projections of device speed)	1.75
Voltage scaling projected	0.81
Capacitance scaling projected	0.39
Energy per switched transistor scaling (CV^2)	0.26
Power scaling assuming fraction of transistors switching is the same and chip exhibits full frequency scaling	1.79

Figure 5.36 A comparison of the 22 nm technology of 2016 with a future 11 nm technology, likely to be available sometime between 2022 and 2024. The characteristics of the 11 nm technology are based on the International Technology Roadmap for Semiconductors, which has been recently discontinued because of uncertainty about the continuation of Moore's Law and what scaling characteristics will be seen.

$$\begin{aligned}\text{Power} &= \text{Energy per Transistor} \times \text{Frequency} \times \text{Transistors switched} \\ &= \text{Capacitive load} \times \text{Voltage}^2 \times \text{Frequency} \times \text{Transistors switched}\end{aligned}$$

To understand the implications of how energy and power scale, let's compare today's 22 nm technology with a technology projected to be available in 2021–24 (depending on the rate at which Moore's Law continues to slow down). [Figure 5.36](#) shows this comparison based on technology projections and resulting effects on energy and power scaling. Notice that power scaling > 1.0 means that the future device consumes more power; in this case, $1.79 \times$ as much.

Consider the implications of this for one of the latest Intel Xeon processors, the E7-8890, which has 24 cores, 7.2 billion transistors (including almost 70 MiB of cache), operates at 2.2 GHz, has a thermal power rating of 165 watts, and a die size of 456 mm^2 . The clock frequency is already limited by power dissipation: a 4-core version has a clock of 3.2 GHz, and a 10-core version has a 2.8 GHz clock. With the 11 nm technology, the same size die would accommodate 96 cores with almost 280 MiB of cache and operate at a clock rate (assuming perfect frequency scaling) of 4.9 GHz. Unfortunately, with all cores operating and no efficiency improvements, it would consume $165 \times 1.79 = 295$ watts. If we assume the 165-W heat dissipation limit remains, then only 54 cores can be active. This limit yields a maximum performance speedup of $54/24 = 2.25$ over a 5–6 year period, less than one-half the performance scaling seen in the late 1990s. Furthermore, we may have Amdahl's Law effects, as the next example shows.

Example Suppose we have a 96-core future generation processor, but on average only 54 cores can be busy. Suppose that 90% of the time, we can use all available cores; 9% of the time, we can use 50 cores; and 1% of the time is strictly serial. How much speedup might we expect? Assume that cores can be turned off when not in use and draw no power and assume that the use of a different number of cores is distributed so that we need to worry only about average power consumption. How would the

multicore speedup compare to the 24-processor count version that can use all its processor 99% of the time?

Answer We can find how many cores can be used for the 90% of the time when more than 54 are usable, as follows:

$$\begin{aligned}\text{Average Processor Usage} &= 0.09 \times 50 + 0.01 \times 1 + 0.90 \times \text{Max processor} \\ 54 &= 4.51 + 0.90 \times \text{Max processor} \\ \text{Max processor} &= 55\end{aligned}$$

Now, we can find the speedup:

$$\begin{aligned}\text{Speedup} &= \frac{1}{\frac{\text{Fraction}_{55}}{55} + \frac{\text{Fraction}_{50}}{50} + (1 - \text{Fraction}_{55} - \text{Fraction}_{50})} \\ \text{Speedup} &= \frac{1}{\frac{0.90}{55} + \frac{0.09}{50} + 0.01} = 35.5\end{aligned}$$

Now compute the speedup on 24 processors:

$$\begin{aligned}\text{Speedup} &= \frac{1}{\frac{\text{Fraction}_{24}}{24} + (1 - \text{Fraction}_{24})} \\ \text{Speedup} &= \frac{1}{\frac{0.99}{24} + 0.01} = 19.5\end{aligned}$$

When considering both power constraints and Amdahl's Law effects, the 96-processor version achieves less than a factor of 2 speedup over the 24-processor version. In fact, the speedup from clock rate increase nearly matches the speedup from the $4 \times$ processor count increase. We comment on these issues further in the concluding remarks.

5.11

Concluding Remarks

As we saw in the previous section, multicore does not magically solve the power problem because it clearly increases both the transistor count and the active number of transistors switching, which are the two dominant contributions to power. The failure of Dennard scaling merely makes it more extreme.

But multicore does alter the game. By allowing idle cores to be placed in power-saving mode, some improvement in power efficiency can be achieved, as the results in this chapter have shown. For example, shutting down cores in the Intel i7 allows other cores to operate in Turbo mode. This capability allows a trade-off between higher clock rates with fewer processors and more processors with lower clock rates.

More importantly, multicore shifts the burden for keeping the processor busy by relying more on TLP, which the application and programmer are responsible for

identifying, rather than on ILP, for which the hardware is responsible. Multiprogrammed and highly parallel workloads that avoid Amdahl's Law effects will benefit more easily.

Although multicore provides some help with the energy efficiency challenge and shifts much of the burden to the software system, there remain difficult challenges and unresolved questions. For example, attempts to exploit thread-level versions of aggressive speculation have so far met the same fate as their ILP counterparts. That is, the performance gains have been modest and are likely less than the increase in energy consumption, so ideas such as speculative threads or hardware run-ahead have not been successfully incorporated in processors. As in speculation for ILP, unless the speculation is almost always right, the costs exceed the benefits.

Thus, at the present, it seems unlikely that some form of simple multicore scaling will provide a cost-effective path to growing performance. A fundamental problem must be overcome: finding and exploiting significant amounts of parallelism in an energy- and silicon-efficient manner. In the previous chapter, we examined the exploitation of data parallelism via a SIMD approach. In many applications, data parallelism occurs in large amounts, and SIMD is a more energy-efficient method for exploiting data parallelism. In the next chapter, we explore large-scale cloud computing. In such environments, massive amounts of parallelism are available from millions of independent tasks generated by individual users. Amdahl's Law plays little role in limiting the scale of such systems because the tasks (e.g., millions of Google search requests) are independent. Finally, in [Chapter 7](#), we explore the rise of domain-specific architectures (DSAs). Most domain-specific architectures exploit the parallelism of the targeted domain, which is often data parallelism, and as with GPUs, DSAs can achieve much higher efficiency as measured by energy consumption or silicon utilization.

In the last edition, published in 2012, we raised the question of whether it would be worthwhile to consider heterogeneous processors. At that time, no such multicore was delivered or announced, and heterogeneous multiprocessors had seen only limited success in special-purpose computers or embedded systems. While the programming models and software systems remain challenging, it appears inevitable that multiprocessors with heterogeneous processors will play an important role. Combining domain-specific processors, like those discussed in [Chapters 4 and 7](#), with general-purpose processors is perhaps the best road forward to achieve increased performance and energy efficiency while maintaining some of the flexibility that general-purpose processors offer.

5.12

Historical Perspectives and References

Section M.7 (available online) looks at the history of multiprocessors and parallel processing. Divided by both time period and architecture, the section features discussions on early experimental multiprocessors and some of the great debates in parallel processing. Recent advances are also covered. References for further reading are included.

Case Studies and Exercises by Amr Zaky and David A. Wood

Case Study 1: Single Chip Multicore Multiprocessor

Concepts illustrated by this case study

- Snooping Coherence Protocol Transitions
- Coherence Protocol Performance
- Coherence Protocol Optimizations
- Synchronization

A multicore SMT multiprocessor is illustrated in Figure 5.37. Only the cache contents are shown. Each core has a single, private cache with coherence maintained using the snooping coherence protocol of Figure 5.7. Each cache is direct-mapped, with four lines, each holding 2 bytes (to simplify diagram). For further simplification, the whole line addresses in memory are shown in the address fields in the caches, where the tag would normally exist. The coherence states are denoted M, S, and I for Modified, Shared, and Invalid.

5.1. [10/10/10/10/10/10/10] <5.2> For each part of this exercise, the initial cache and memory state are assumed to initially have the contents shown in Figure 5.37. Each part of this exercise specifies a sequence of one or more CPU operations of the form

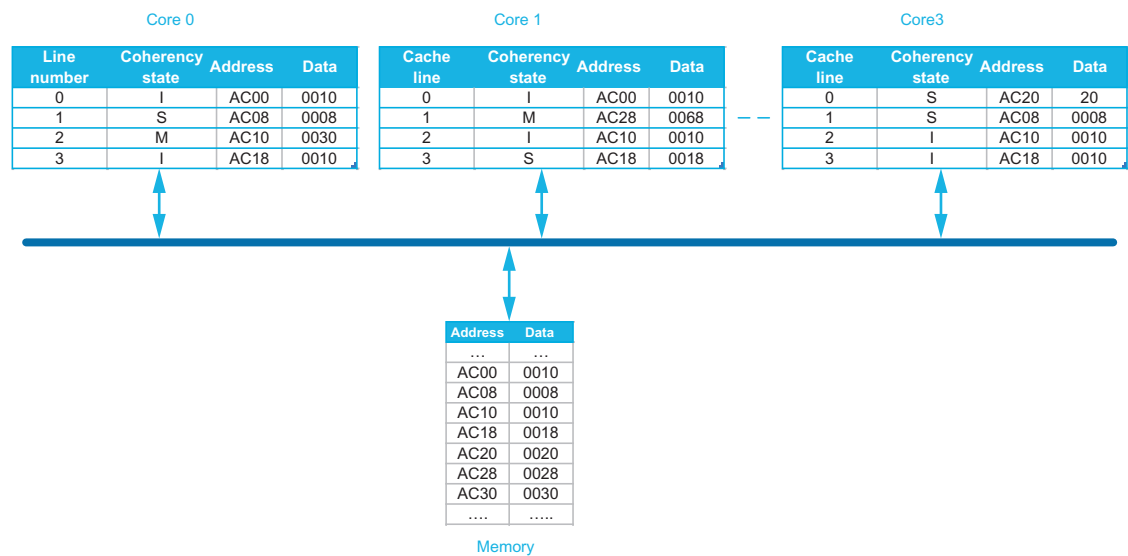

Figure 5.37 Multicore (point-to-point) multiprocessor.

Ccore#: R, <address> for reads

and

Ccore#: W, <address> <-- <value written> for writes.

For example,

C3: R, AC10 & C0: W, AC18 <-- 0018

Read and write operations are for 1 byte at a time. Show the resulting state (i.e., coherence state, tags, and data) of the caches and memory after the actions given below. Show only the cache lines that experience some state change; for example:

C0.L0: (I, AC20, 0001) indicates that line 0 in core 0 assumes an “invalid” coherence state (I), stores AC20 from the memory, and has data contents 0001. Furthermore, represent any changes to the memory state as M: <address> <- value.

Different parts (a) through (g) do not depend on one another: assume the actions in all parts are applied to the initial cache and memory states.

- a. [10] <5.2> C0: R, AC20
- b. [10] <5.2> C0: W, AC20 <-- 80
- c. [10] <5.2> C3: W, AC20 <-- 80
- d. [10] <5.2> C1: R, AC10
- e. [10] <5.2> C0: W, AC08 <-- 48
- f. [10] <5.2> C0: W, AC30 <-- 78
- g. [10] <5.2> C3: W, AC30 <-- 78

- 5.2. [20/20/20/20] <5.3> The performance of a snooping cache-coherent multiprocessor depends on many detailed implementation issues that determine how quickly a cache responds with data in an exclusive or M state block. In some implementations, a processor read miss to a cache block that is exclusive in another processor’s cache is faster than a miss to a block in memory. This is because caches are smaller, and thus faster, than main memory. Conversely, in some implementations, misses satisfied by memory are faster than those satisfied by caches. This is because caches are generally optimized for “front side” or CPU references, rather than “back side” or snooping accesses. For the multiprocessor illustrated in [Figure 5.37](#), consider the execution of a sequence of operations on a single processor core where

- read and write hits generate no stall cycles;
- read and write misses generate N_{memory} and N_{cache} stall cycles if satisfied by memory and cache, respectively;
- write hits that generate an invalidate incur $N_{\text{invalidate}}$ stall cycles; and
- a write-back of a block, either due to a conflict or another processor’s request to an exclusive block, incurs an additional $N_{\text{writeback}}$ stall cycles.

Consider two implementations with different performance characteristics summarized in [Figure 5.38](#).

Parameter	Implementation 1 Cycles	Implementation 2 Cycles
N_{memory}	100	100
N_{cache}	40	130
$N_{invalidate}$	15	15
$N_{writeback}$	10	10

Figure 5.38 Snooping coherence latencies.

To observe how these cycle values are used, we illustrate how the following sequence of operations, assuming the initial caches' states in [Figure 5.37](#), behave under implementation 1.

C1: R, AC10
C3: R, AC10

For simplicity, assume that the second operation begins after the first completes, even though they are on different processor cores.

For Implementation 1,

- the first read generates 50 stall cycles because the read is satisfied by C0's cache: C1 stalls for 40 cycles while it waits for the block, and C0 stalls for 10 cycles while it writes the block back to memory in response to C1's request; and
- the second read by C3 generates 100 stall cycles because its miss is satisfied by memory.

Therefore this sequence generates a total of 150 stall cycles.

For the following sequences of operations, how many stall cycles are generated by each implementation?

- a. [20] <5.3> C0: R, AC20
C0: R, AC28
C0: R, AC30
- b. [20] <5.3> C0: R, AC00
C0: W, AC08 <-- 48
C0: W, AC30 <-- 78
- c. [20] <5.3> C1: R, AC20
C1: R, AC28
C1: R, AC30
- d. [20] <5.3> C1: R, AC00
C1: W, AC08 <-- 48
C1: W, AC30 <-- 78

- 5.3. [20] <5.2> Some applications read a large dataset first and then modify most or all of it. The base MSI coherence protocol will first fetch all of the cache blocks in the Shared state and then be forced to perform an invalidate operation to upgrade them to the

Modified state. The additional delay has a significant impact on some workloads. The MESI addition to the standard protocol (see [Section 5.2](#)) provides some relief in these cases. Draw new protocol diagrams for a MESI protocol that adds the Exclusive state and transitions to the base MSI protocol's Modified, Shared, and Invalidate states.

- 5.4. [20/20/20/20/20] <5.2> Assume the cache contents of [Figure 5.37](#) and the timing of Implementation 1 in [Figure 5.38](#). What are the total stall cycles for the following code sequences with both the base protocol and the new MESI protocol in Exercise 5.3? Assume state transitions that require zero interconnect transactions incur no additional stall cycles.
- [20] <5.2> C0: R, AC00
C0: W, AC00 <-- 40
 - [20] <5.2> C0: R, AC20
C0: W, AC20 <-- 60
 - [20] <5.2> C0: R, AC00
C0: R, AC20
 - [20] <5.2> C0: R, AC00
C1: W, AC00 <-- 60
 - [20] <5.2> C0: R, AC00
C0: W, AC00 <-- 60
C1: W, AC00 <-- 40
- 5.5. Code running on a single core and not sharing any variables with other cores can suffer some performance degradation because of the snooping coherence protocol. Consider the two following iterative loops are NOT functionally equivalent but they seem similar in complexity. One could be led to conclude that they would spend a comparably close number of cycles when executed on the same processor core.

Loop 1	Loop 2
Repeat i: 1 .. n	Repeat i: 1 .. n
A[i] <-- A[i-1] + B[i];	A[i] <-- A[i] + B[i];

Assume that

- every cache line can hold exactly one element of A or B;
- arrays A and B do not interfere in the cache; and
- all the elements of A or B are in the cache before either loop is executed.

Compare their performance when run on a core whose cache uses the **MESI coherence** protocol. Use the stall cycles data for Implementation 1 in [Figure 5.38](#).

Assume that a cache line can hold multiple elements of A and B (A and B go to separate cache lines). How will this affect the relative performances of Loop1 and Loop2?

Suggest hardware and/or software mechanisms that would improve the performance of Loop1 on a single core.

- 5.6. [20] <5.2> Many snooping coherence protocols have additional states, state transitions, or bus transactions to reduce the overhead of maintaining cache coherency. In Implementation 1 of Exercise 5.2, misses are incurring fewer stall cycles when they are supplied by cache than when they are supplied by memory. The MOESI protocol extension (see [Section 5.2](#)) addresses this need.

Draw new protocol diagrams with the additional state and transitions.

- 5.7. [20/20/20/20] <5.2> For the following code sequences and the timing parameters for the two implementations in [Figure 5.36](#), compute the total stall cycles for the base MSI protocol and the optimized MESI protocol in Exercise 5.3. Assume state transitions that do not require bus transactions incur no additional stall cycles.

- a. [20] <5.2> C1: R, AC10
C3: R, AC10
C0: R, AC10
- b. [20] <5.2> C1: R, AC20
C3: R, AC20
C0: R, AC20
- c. [20] <5.2> C0: W, AC20 <-- 80
C3: R, AC20
C0: R, AC20
- d. [20] <5.2> C0: W, AC08 <-- 88
C3: R, AC08
C0: W, AC08 <-- 98

- 5.8. [20/20/20/20] <5.5> The spin lock is the simplest synchronization mechanism possible on most commercial shared-memory machines. This spin lock relies on the exchange primitive to atomically load the old value and store a new value. The lock routine performs the exchange operation repeatedly until it finds the lock unlocked (i.e., the returned value is 0).

```

        addi x2, x0, #1
lockit: EXCH x2, 0(x1)
        bnez x2, lockit

```

The lock is released simply by storing a 0 into x2.

As discussed in [Section 5.5](#), the more optimized spin lock employs cache coherence and uses a load to check the lock, allowing it to spin with a shared variable in the cache.

```

lockit: ld      x2, 0(x1)
        bnez   x2, lockit
        addi   x2, x0, #1
        EXCH   x2, 0(x1)
        bnez   x2, lockit

```

Assume that processor cores C0, C1, and C3 are all trying to acquire a lock at address 0xAC00 (i.e., register R1 holds the value 0xAC00). Assume the cache contents from Figure 5.37 and the timing parameters from Implementation 1 in Figure 5.38. For simplicity, assume the critical sections are 1000 cycles long.

- a. [20] <5.5> Using the simple spin lock, determine *approximately* how many memory stall cycles each processor incurs before acquiring the lock.
- b. [20] <5.5> Using the optimized spin lock, determine *approximately* how many memory stall cycles each processor incurs before acquiring the lock.
- c. [20] <5.5> Using the simple spin lock, *approximately* how many memory accesses occur?
- d. [20] <5.5> Using the optimized spin lock, *approximately* how many memory accesses occur?

Case Study 2: Simple Directory-Based Coherence

Concepts illustrated by this case study

- Directory Coherence Protocol Transitions
- Coherence Protocol Performance
- Coherence Protocol Optimizations

Consider the distributed shared-memory system illustrated in Figure 5.39. It consists of 8 nodes of processor cores organized as three-dimensional hypercube with point-to-point interconnections, as shown in the figure. For simplification, we assume the following scaled-down configuration:

- Every node has a *single processor core* with a direct-mapped L1 data cache with its dedicated cache controller.
- The L1 data cache has a capacity of two cache lines with a line size of B bytes.
- The L1 cache states are denoted M, S, and I for Modified, Shared, and Invalid. An example cache entry in some would like

1: S, M3, 0xabcd -->

Cache line 1 is in the “Shared” state; it contains memory block M3 and the data value of the block is 0xabcd.

- The system memory comprises 8 memory blocks (i.e., one memory block per node) and is distributed among the eight nodes, with every node owning a memory block. Node C_i owns memory block M_i .
- Each memory block is B-bytes wide and is tracked by a coherency directory entry stored with the memory block.

Figure 5.39 Multicore multiprocessor with DSM.

- The state of each memory directory entry is denoted DM, DS, and DI for Directory Modified, Directory Shared, and Directory Invalid. Additionally, the directory entry lists the block sharers using a bit vector with 1 bit for every node. Here is an example memory block and associated directory entry:

M3: 0xABCD, DS, 00000011 -->

Memory block M3 (in node C3) contains the value 0xABCD and is shared by nodes 0 and 1 (corresponding to 1s in the bit vector).

Read/Write Notation

To describe read/write transactions, we will use the notation

$C_i\#$: R, $\langle M_i \rangle$ for reads

and

$C_i\#$: W, $\langle M_i \rangle$ <-- $\langle \text{value written} \rangle$ for writes.

For example,

C3: R, M2 describes the core in node 3 issuing a read transaction from an address at memory block M2 (the address may possibly be cached in C3 already).

C0: W, M3 <-- 0018 describes the core in node 0 issuing a write transaction (data is 0X0018) to an address at memory block M3 (the address may possibly be cached in C0 already).

Messages

The directory coherency schemes depend on exchange of command and/or data messages as described by the directory protocol described in [Figure 5.20](#). An example of a command message is a read request. An example of a data message is a read response (with data included).

- Messages originating and ending in the same node do not cross any inter-node links.
- Message with distinct source/destination nodes travel through inter-node links. These messages may be destined from one cache controller to another, from a cache controller to a directory controller, or from a directory controller to a cache controller.
- Messages traveling from a source node to a distinct destination node are statically routed.
 - The static routing algorithm selects a shortest path between the source and destination nodes.
 - The short path is determined by considering the binary representations of the source and destination indices (e.g., 001 for node C1 and 100 for node C4), then by moving from one node to a neighboring node that was not already crossed by the message.
 - For example, to go from node 6 to node 0 (110 --> 000), the path is 110 --> 100 --> 000.
 - Because more than one shortest path may exist (110 --> 010 --> 000 is another path for the preceding example), we assume that the path is selected by inverting first the least significant bit that is different from the corresponding bit in destination index. For example, to travel from node 1 to node 6 (001 --> 110), the path is 001 --> 000 --> 010 --> 110.
 - The longest possible path traveled by any message has 3 links (equal to the number of bits in the binary representation of a node index).
- A node can simultaneously process up to three messages from/to distinct neighboring nodes' links if no two of them are competing for the same link resource as clarified by the following examples of **messages sent/received to/from/through** node 000.

Messages: from 001 --> 010; 010 --> 000 (to cache/directory controller); 100 --> 001. **OK** (distinct destinations).

Message: from 001 --> 010; 000 --> 001 (from cache/directory controller); 100 --> 001.

Not OK as two messages are destined to node 001

In case of destination contention, ties are broken assigning priority to

- a. message destined to the node (000 in example) cache or directory controller; then
- b. messages forwarded from one to another (through 000 in example); then
- c. messages originating from the node (000 in example) cache or directory controller.

- Assume the transmission and service delays in the following table.

Message type	Cache controller	Directory controller	Link
No data	2 cycles	5 cycles	10 cycles
With data	$(3 + \lceil B/4 \rceil)$ cycles	$(6 + 10 * B)$ cycles	$(4 + B)$

- If a message is forwarded through a node, it is first completely received by the node before being sent to the next node on the path.
- Assume any cache controller; directory controller has unlimited capacity to enqueue messages and service them in FCFS order.

- 5.9. [10/10/10] <5.4> For each part of this exercise, assume that initially all caches lines are invalid, and the data in memory M_i is the byte i ($0 \times 00 \leq i \leq 0 \times 07$) repeated as many times as the block size. Assume that successive requests are completely serialized. That is, no core will issue a coherency request until the previous request (by same or different core) is completed.

For each of the following parts,

- show the final state (i.e., coherence state, sharers/owners, tags, and data) of the caches and directory controller (including data values) after the given transaction sequence has completed; and
- show the messages transferred (choose a suitable format for message types).
 - a. [10] <5.4> C3: R, M4
 C3: R, M2
 C7: W, M4 <--0xaaaa
 C1: W, M4 <--0xbbbb
 - b. [10] <5.4> C3: R, M0
 C3: R, M2
 C6: W, M4 <--0xaaaa
 C3: W, M4 <--0xbbbb

c. [10] <5.4> C0: R, M7
 C3: R, M4
 C6: W, M2 <--0xaaaa
 C2: W, M2 <--0xbbbb

- 5.10. [10/10/10] <5.4> The directory protocol used in 5.9 (based on [Figure 5.20](#)) assumes that the directory controller receives requests, sends invalidates, receives modified data, sends modified data to requester if block was dirty, and so on. Assume now that the directory controller will delegate some work to the cores. For example, it will notify the exclusive owner of a modified block when some other core needs the block and will have the owner send the block to the new sharer. Specifically, consider the following optimizations and indicate what their benefits (if any) are. Also, specify how the messages will be modified (in comparison with [Figure 5.20](#) protocol) to support the new change.

Hint: Benefits might be reduction in number of messages, faster response time, and so on.

- a. [10] <5.4> On a write miss to a shared memory block, the directory controller sends the data to the requester and instructs the sharers to send their invalidate acknowledgements directly to the requester.
 - b. [10] <5.4> On a read miss to a block modified in some other core, the directory controller instructs the owner of the modified copy to directly forward the data to the requester.
 - c. [10] <5.4> On a read miss to a block in shared (S) state in some other cores, the directory controller instructs one of the sharers (say, the one closest to the requester) to directly forward the data to the requester.
- 5.11. [15/15/15] <5.4> In problem 5.9, it was assumed that all transactions on the system were serially executed, which is both unrealistic and inefficient in a DSM multicore. We now relax this condition. We will require only that all transactions originating in one core are serialized. However, different cores can independently issue their read/write transactions and even compete for the same memory block. The transactions of problem 5.9 are represented next to reflect the new, relaxed constraints. Redo problem 5.9 with the new, relaxed constraints.

- a. [15] <5.4>
 C1: W, M4 <--0xbbbb C3: R, M4 C7: R, M2
 C3: W, M4 <--0xaaaa
- b. [15] <5.4>
 C3: R, M0 C6: W, M4 <--0xaaaa
 C3: R, M2
 C3: W, M4 <--0xbbbb
- c. [15] <5.4>
 C0: R, M7 C2: W, M2 <--0xbbbb C3: R, M4 C6: W, M2 <--0xaaaa

- 5.12. [10/10] <5.4> Use the routing and delay information described earlier and trace how the following groups of transactions will progress in the system (assume that all accesses are misses).

- a. C0: R, M7 C2: W, M2 <-- 0xbbbb C3: R, M4 C6: W, M2 <-- 0xaaaa

Show how the following transaction groups (performed one at a time in series) will proceed under both approaches.

Case Study 3: Memory Consistency

Concepts Illustrated by This Case Study

- Legitimate Program Behavior Under Sequential Consistency (SC) Models
- Hardware Optimization Allowed for SC Models
- Using Synchronization Primitives to Make a Consistency Model Emulate a More Restrictive Model

P1:	P2:
While (B == 0); A=1;	While (A==0); B = 1;

- a. If the processors adhere to sequential consistency (SC) consistency model. What are the possible values of A and B at the end of the segments? Show the statement interleaving supporting your answer(s).
 - b. Repeat (a) if the processors adhere to the total store order (TSO) consistency model.
- [5] <5.6> Consider the following code segments running on two processors P1 and P2. Assume A, and B, are initially 0. Explain how an optimizing compiler might make it impossible for B to be ever set to 2 in a sequentially consistent execution model.

P1:	P2:
A=1;	B=1;
A=2;	While (A <> 1);
While (B == 0);	B = 2;

- 5.17. [10] <5.4>. In a processor implementing a SC consistency model, the data cache is augmented with a data prefetch unit. Will that alter the SC implementation execution results? Why or why not?

- 5.18. [10/10] <5.6> Assume that the following code segment is executed on a processor that implements partial store order (PSO),

```
A=1;
B=2;
If (C== 3)
D=B;
```

- Augment the code with synchronization primitives to make it emulate the behavior of a total store order (TSO) implementation.
 - Augment the code with synchronization primitives to make it emulate the behavior of a sequential consistency (SC) implementation.
- 5.19. [20/20/20] <5.6> Sequential consistency (SC) requires that all reads and writes appear to have executed in some total order. This may require the processor to stall in certain cases before committing a read or write instruction. Consider the code sequence

```
write A
read B
```

where the write A results in a cache miss and the read B results in a cache hit.

Under SC, the processor must stall read B until after it can order (and thus perform) write A. Simple implementations of SC will stall the processor until the cache receives the data and can perform the write.

Release consistency (RC) consistency mode (see [Section 5.6](#)) relaxes these constraints: ordering—when desired—is enforced by judicious use of synchronization operations. This allows, among other optimizations, processors to implement write buffers, which hold committed writes that have not yet been ordered with respect to other processors' writes. Reads can pass (and potentially bypass) the write buffer in RC (which they could not do in SC).

Assume that one memory operation can be performed per cycle and that operations that hit in the cache or that can be satisfied by the write buffer introduce no stall cycles. Operations that miss incur the latencies listed in [Figure 5.38](#).

How many stall cycles occur *prior* to each operation for both the SC and RC consistency models? (Write buffer can hold at most one write.)

- [20] <5.6> P0: write 110 <-- 80 //assume miss (no other cache has the line)
P0: read 108 //assume miss (no other cache has the line)

- b. [20]
<5.6>
P0: read 110
//assume miss (no other cache has the line)
P0: write 100 <-- 90
//assume hit

c. [20]
<5.6>
P0: write 100 <-- 80
//assume miss
P0: write 110 <-- 90
//assume hit
- 5.20. [20] <5.6> Repeat part (a) of problem 5.19 under an SC model on a processor that has a read prefetch unit. Assume a read prefetch was triggered 20 cycles in advance of the write operation.

Exercises

- 5.21. [15] <5.1> Assume that we have a function for an application of the form $F(i, p)$, which gives the fraction of time that exactly i processors are usable given that a total of p processors are available. This means that
- $$\sum_{i=1}^p F(i, p) = 1$$
- Assume that when i processors are in use, the applications run i times faster.
- a. Rewrite Amdahl’s Law so that it gives the speedup as a function of p for some application.

b. An application A runs on single processor for a time T seconds. Different portions of its running time can improve if a larger number of processors is used. [Figure 5.40](#) provides the details. How much speedup will A achieve when on 8 processors?

c. Repeat for 32 processors and an infinite number of processors.
- 5.22. [15/20/10] <5.1> In this exercise, we examine the effect of the interconnection network topology on the CPI of programs running on a 64-processor distributed-memory multiprocessor. The processor clock rate is 2.0 GHz, and the base CPI of an application with all references hitting in the cache is 0.75. Assume that 0.2% of the instructions involve a remote communication reference. The cost of a remote communication reference is $(100 + 10h)$ ns, h being the number of communication network hops that a remote reference has to make to the remote processor memory and back. Assume all communication links are bidirectional.
- a. [15] <5.1> Calculate the worst-case remote communication cost when the 64 processors are arranged as a ring, as an 8×8 processor grid, or as a hypercube (hint: longest communication path on a 2^n hypercube has n links).

Fraction of T	20%	20%	10%	5%	15%	20%	10%
Processors (P)	1	2	4	6	8	16	128

Figure 5.40
Percentage of application’s A time that can use up to P processors.

- b. [20] <5.1> Compare the base CPI of the application with no remote communication to the CPI achieved with each of the three topologies in part (a).
- 5.23. [15] <5.2> Show how the basic snooping protocol of [Figure 5.6](#) can be changed for a write-through cache. What is the major hardware functionality that is not needed with a write-through cache compared with a write-back cache?
- 5.24. [20/20] <5.2> Please answer the following problems:
 - a. [20] <5.2> Add a clean exclusive state to the basic snooping cache coherence protocol ([Figure 5.6](#)). Show the protocol in the finite state machine format used in the figure.
 - b. [20] <5.2> Add an “owned” state to the protocol of part (a) and describe using the same finite state machine format used in [Figure 5.6](#).
- 5.25. [15] <5.2> One proposed solution for the problem of false sharing is to add a valid bit per word. This would allow the protocol to invalidate a word without removing the entire block, letting a processor keep a portion of a block in its cache while another processor writes a different portion of the block. What extra complications are introduced into the basic snooping cache coherence protocol ([Figure 5.6](#)) by this addition? Consider all possible protocol actions.
- 5.26. [15/20] <5.3> This exercise studies the impact of aggressive techniques to exploit instruction-level parallelism in the processor when used in the design of shared-memory multiprocessor systems. Consider two systems identical except for the processor. System A uses a processor with a simple single-issue, in-order pipeline, and system B uses a processor with four-way issue, out-of-order execution and a reorder buffer with 64 entries.
 - a. [15] <5.3> Following the convention of [Figure 5.11](#), let us divide the execution time into instruction execution, cache access, memory access, and other stalls. How would you expect each of these components to differ between system A and system B?
 - b. [10] <5.3> Based on the discussion of the behavior of OLTP workload in [Section 5.3](#), what is the important difference between the OLTP workload and other benchmarks that limit benefit from a more aggressive processor design?
- 5.27. [15] <5.3> How would you change the code of an application to avoid false sharing? What might be done by a compiler and what might require programmer directives?
- 5.28. [15] <5.3> An application is calculating the number of occurrences of a certain word in a very large number of documents. A very large number of processors divided the work, searching the different documents. They created a huge array—word_count—of 32-bit integers, every element of which is the number of times the word occurred in some document. In a second phase, the computation is moved to a small SMP server with four processors. Each processor sums up approximately $\frac{1}{4}$ of the array elements. Later, one processor calculates the total sum.

```

for (int p=0; p<=3; p++) // Each iteration of is executed on a
                        separate processor.
{
    sum[p] = 0;
    for (int i=0; i<n/4; i++) // n is size of word_count and
                            is divisible by 4
        sum[p] = sum[p] + word_count[p+4*i];
}
total_sum = sum[0] + sum[1] + sum[2] + sum[3] //executed only
                                              on processor.

```

- a. Assuming each processor has a 32-byte L1 data cache. Identify the cache line sharing (true or false) that the code exhibits.
 - b. Rewrite the code to reduce the number of misses to elements of the array `word_count`.
 - c. Identify a manual fix you can make to the code to rid it of any false sharing.
- 5.29. [15] <5.4> Assume a directory-based cache coherence protocol. The directory currently has information that indicates that processor P1 has the data in “exclusive” mode. If the directory now gets a request for the same cache block from processor P1, what could this mean? What should the directory controller do? (Such cases are called “race conditions” and are the reason why coherence protocols are so hard to design and verify.)
- 5.30. [20] <5.4> A directory controller can send invalidates for lines that have been replaced by the local cache controller. To avoid such messages, and to keep the directory consistent, replacement hints are used. Such messages tell the controller that a block has been replaced. Modify the directory coherence protocol of [Section 5.4](#) to use such replacement hints.
- 5.31. [20/15/20/15] <5.4> One downside of a straightforward implementation of directories using fully populated bit vectors is that the total size of the directory information scales as the product: processor count \times memory blocks. If memory grows linearly with processor count, the total size of the directory grows quadratically in the processor count. In practice, because the directory needs only 1 bit per memory block (which is typically 32–128 bytes), this problem is not serious for small-to-moderate processor counts. For example, assuming a 128-byte block, and P processors, the amount of directory storage compared to main memory is $P/(128*8) = P/1024$, which is 12.5% overhead for $P = 128$ processors. We can avoid this problem by observing that we need to keep only an amount of information that is proportional to the cache size of each processor. We explore some solutions in these exercises.
- a. [20] <5.4> One method to obtain a scalable directory protocol is to organize the multiprocessor as a logical hierarchy with the processors as leaves of the hierarchy and directories positioned at the root of each subtree. The directory at each subtree records which descendants cache which memory blocks. It also

records the memory blocks—with a home in that subtree—that are cached outside the subtree. Compute the amount of storage needed to record the processor information for the directories, assuming that each directory is fully associative. Your answer should incorporate both the number of nodes at each level of the hierarchy as well as the total number of nodes.

- b. [15] <5.4> Another approach to reducing the directory size is to allow only a limited number of the directory's memory blocks to be shared at any given time. Implement the directory as a four-way set-associative cache storing full bit vectors. If a directory cache miss occurs, choose a directory entry and invalidate the entry. Describe how this organization will work elaborating what will happen as a block read, written replaced and written back to memory. Modify the protocol in Figure 5.20 to reflect the new transitions required by this directory organization.
 - c. [20] <5.4> Rather than reducing the number of directory entries, we can implement bit vectors that are not dense. For example, we can set every directory entry to 9 bits. If a block is cached in only one node outside its home, this field contains the node number. If the block is cached in more than one node outside its home, this field is a bit vector with each bit indicating a group of eight processors, at least one of which caches the block. Illustrate how this scheme would work for a 64-processor DSM machine that consists of eight 8-processors groups.
 - d. [15] An extreme approach to reducing the directory size is to implement an "empty" directory; that is, the directory in every processor does not store any memory states. It receives requests and forwards them as *appropriate*. What is the benefit of having such a directory over having no directory at all for a DSM system?
- 5.32. [10] <5.5> Implement the classical compare-and-swap instruction using the *load linked/store conditional* instruction pair.
- 5.33. [15] <5.5> One performance optimization commonly used is to pad synchronization variables so as not to have any other useful data in the same cache line. Construct an example demonstrating that this optimization can be extremely useful in some situations. Assume a snoopy write invalidate protocol.
- 5.34. [30] <5.5> One possible implementation of the *load linked/store conditional* pair for multicore processors is to constrain these instructions to using uncached memory operations. A monitor unit intercepts all reads and writes from any core to the memory. It keeps track of the source of the *load linked* instructions and whether any intervening stores occur between the *load linked* and its corresponding *store conditional* instruction. The monitor can prevent any failing store conditional from writing any data and can use the interconnect signals to inform the processor that this store failed.

Design such a monitor for a memory system supporting a four-core SMP. Take into account that, generally, read and write requests can have different data sizes (4/8/16/32 bytes). Any memory location can be the target of a *load linked/store*

conditional pair, and the memory monitor should assume that *load linked/store conditional* references to any location can, possibly, be interleaved with regular accesses to the same location. The monitor complexity should be independent of the memory size.

- 5.35. [25] <5.5> Prove that, in a two-level cache hierarchy where L1 is closer to the processor, inclusion is maintained with no extra action if L2 has at least as much associativity as L1, both caches use LRU replacement, and both caches have the same block sizes.
- 5.36. [Discussion] <5> When trying to perform detailed performance evaluation of a multiprocessor system, system designers use one of three tools: analytical models, trace-driven simulation, and execution-driven simulation. Analytical models use mathematical expressions to model the behavior of programs. Trace-driven simulations run the applications on a real machine and generate a trace, typically of memory operations. These traces can be replayed through a cache simulator or a simulator with a simple processor model to predict the performance of the system when various parameters are changed. Execution-driven simulators simulate the entire execution maintaining an equivalent structure for the processor state and so on.
 - a. What are the accuracy/speed trade-offs between these approaches?
 - b. CPU traces, if not carefully collected, can exhibit artifacts of the system they are collected on. Discuss this issue while using branch-prediction and spin-wait synchronization as examples. (Hint: The program itself is not available to a pure CPU trace; just the trace is available.)
- 5.37. [40] <5.7, 5.9> Multiprocessors and clusters usually show performance increases as you increase the number of the processors, with the ideal being n times speedup for n processors. The goal of this biased benchmark is to make a program that gets worse performance as you add processors. For example, this means that one processor on the multiprocessor or cluster runs the program fastest, two are slower, four are slower than two, and so on. What are the key performance characteristics for each organization that give inverse linear speedup?

Warehouse-Scale Computers to Exploit Request-Level and Data-Level Parallelism

The datacenter is the computer.

Luiz André Barroso,
Google (2007)

A hundred years ago, companies stopped generating their own power with steam engines and dynamos and plugged into the newly built electric grid. The cheap power pumped out by electric utilities didn't just change how businesses operate. It set off a chain reaction of economic and social transformations that brought the modern world into existence. Today, a similar revolution is under way. Hooked up to the Internet's global computing grid, massive information-processing plants have begun pumping data and software code into our homes and businesses. This time, it's computing that's turning into a utility.

Nicholas Carr,
*The Big Switch: Rewiring the World, from
Edison to Google (2008)*

6.1

Introduction

Anyone can build a fast CPU. The trick is to build a fast system.

Seymour Cray,

Considered the father of the supercomputer

The warehouse-scale computer (WSC)¹ is the foundation of Internet services billions of people use every day: search, social networking, online maps, video sharing, online shopping, email services, and so on. The tremendous popularity of such Internet services necessitated the creation of WSCs that could keep up with the rapid demands of the public. Although WSCs may appear to be just large data centers, their architecture and operation are quite different, as we will see. Today's WSCs act as one giant machine that costs hundreds of million dollars for the building, the electrical and cooling infrastructure, the servers, and the networking equipment that connects and houses 50,000–100,000 servers. Moreover, the rapid growth of commercial cloud computing (see [Section 6.5](#)) makes WSCs accessible to anyone with a credit card.

Computer architecture extends naturally to designing WSCs. For example, Luiz Barroso of Google (quoted earlier) did his dissertation research in computer architecture. He believes that an architect's skills of designing for scale, designing for dependability, and a knack for debugging hardware are very helpful in the creation and operation of WSCs.

At this leading-edge scale, which requires innovation in power distribution, cooling, monitoring, and operations, the WSC is the modern descendant of the supercomputer—making Seymour Cray the godfather of today's WSC architects. His extreme computers handled computations that could be done nowhere else, but were so expensive that only a few companies could afford them. This time the target is providing information technology for the world instead of high-performance computing (HPC) for scientists and engineers; thus WSCs arguably play a more important role for society today than Cray's supercomputers did in the past.

Unquestionably, WSCs have many orders of magnitude more users than high-performance computing, and they represent a much greater share of the IT market. Whether measured by the number of users or revenue, Google is 1000 times larger than Cray Research ever was.

¹This chapter is based on material from the book *The Datacenter as a Computer: An Introduction to the Design of Warehouse-Scale Machines, Second Edition*, by [Luiz André Barroso](#), [Jimmy Clidaras](#), and [Urs Hölzle of Google \(2013\)](#); the blog *Perspectives* at [mvdirona.com](#) and the talks “Cloud-Computing Economies of Scale” and “Data Center Networks Are in My Way,” by [James Hamilton of Amazon Web Services \(2009, 2010\)](#); and the paper *Above the Clouds: A View of Cloud Computing*, by [Michael Armbrust et al. \(2010\)](#).

WSC architects share many goals and requirements with server architects:

- *Cost-performance*—Work done per dollar is critical in part because of the scale. Reducing the costs of a collection of WSCs by few percent could save millions of dollars.
- *Energy efficiency*—Except for the photons that leave WSCs, they are essentially closed systems, with almost all the energy consumed turned into heat that must be removed. Thus, peak power and consumed power drive both the cost of power distribution and the cost of cooling systems. The majority of the infrastructure costs of building a WSC goes toward power and cooling. Moreover, energy efficiency is an important part of environmental stewardship. Therefore, work done per joule is critical for both WSCs and its servers because of the high cost of building the power and mechanical infrastructure for a warehouse of computers and for the resulting monthly utility bills.
- *Dependability via redundancy*—The long-running nature of Internet services means that the hardware and software in a WSC must collectively provide at least 99.99% (called “four nines”) of availability; that is, services must be down less than 1 h per year. Redundancy is the key to dependability for both WSCs and servers. Although server architects often utilize more hardware at higher costs to reach high availability, WSC architects rely instead on numerous cost-effective servers connected by a network and redundancy managed by software. In addition to local redundancy inside a WSC, an organization needs redundant WSCs to mask events that can take out whole WSCs. Indeed, although every cloud service needs to be available at least 99.99% of the time, the dependability of a full Internet company like Amazon, Google, or Microsoft needs to be even higher. If one of these companies was completely offline for 1 h per year—that is, 99.99% availability—that would be front page news. Multiple WSCs have the added benefit of reducing latency for services that are widely deployed ([Figures 6.18–6.20](#)).
- *Network I/O*—Server architects must provide a good network interface to the external world, and WSC architects must also. Networking is needed to keep data consistent between multiple WSCs as well as to interface with the public.
- *Both interactive and batch processing workloads*—Although one expects highly interactive workloads for services like search and social networking with billions of users, WSCs, like servers, also run massively parallel batch programs to calculate metadata useful to such services. For example, MapReduce jobs are run to convert the pages returned from crawling the web into search indices (see [Section 6.2](#)).

Not surprisingly, there are also characteristics *not* shared with server architecture:

- *Ample parallelism*—A concern for a server architect is whether the applications in the targeted marketplace have enough concurrency to justify the amount of parallel hardware and whether the cost is too high for sufficient communication

hardware to exploit this parallelism. A WSC architect has no such concern. First, batch applications benefit from the large number of distinct datasets that require independent processing, such as billions of web pages from a web crawl. This processing is *data-level parallelism*, which we saw in [Chapter 4](#), this time applied to data in storage instead of data in memory. Second, interactive Internet service applications, also known as *software as a service (SaaS)*, can benefit from millions of independent users of interactive Internet services. Reads and writes are seldom dependent in SaaS, so SaaS rarely needs to synchronize. For example, search uses a read-only index and email normally reads and writes independent information. We call this type of easy parallelism *request-level parallelism*, as many independent efforts can proceed in parallel naturally with little need for communication or synchronization; an example is that journal-based updating can reduce throughput demands. Even read-/write-dependent features are sometimes dropped to offer storage that can scale to the size of modern WSCs. In any case, WSC applications have no choice but to find algorithms that can scale across hundreds to thousands of servers, as that is what customers expect and that is what the WSC technology provides.

- *Operational costs count*—Server architects typically ignore operational costs of a server, assuming that they pale in comparison to purchase costs. WSCs have longer lifetimes—the building and electrical and cooling infrastructure are often amortized 10–15 years—so the operational costs add up: energy, power distribution, and cooling represent more than 30% of the costs of a WSC over 10 years.
- *Location counts*—To build a WSC, the first step is building a warehouse. One question is where? Real estate agents emphasize location, but the location for a WSC means access to water, inexpensive electricity, proximity to Internet backbone optical fibers, people nearby to work in the WSC, and low risk from environmental disasters, such as earthquakes, floods, and hurricanes. A more obvious concern is just the cost of the land, including enough space to grow the WSC. For companies with many WSCs, another concern is finding a place geographically near a current or future population of Internet users, to reduce latency over the Internet. Other factors include taxes, property costs, social issues (people sometimes want a facility in their country), political issues (some jurisdictions require local hosting), cost of networking, reliability of networking, cost of power, source of power (e.g., hydroelectric versus coal), weather (cooler is cheaper, as [Section 6.4](#) shows), and overall Internet connectivity (Australia is close to Singapore geographically, but the network link bandwidth between them is not great).
- *Computing efficiently at low utilization*—Server architects usually design their systems for peak performance within a cost budget and worry about power only to make sure they don't exceed the cooling capacity of their enclosure. As we will see ([Figure 6.3](#)), WSC servers are rarely fully utilized, in part to ensure low response time and in part to offer the redundancy needed to deliver dependable computing. Given that operational costs count, such servers need to compute efficiently at all utilization levels.
- *Scale and the opportunities/problems associated with scale*—Often extreme computers are extremely expensive because they require custom hardware,

and yet the cost of customization cannot be effectively amortized since few extreme computers are made. However, when purchasing thousands of servers at a time, there *are* great volume discounts. WSCs are so massive internally that there is economy of scale even if there are not many WSCs. As we will see in [Sections 6.5 and 6.10](#), these economies of scale led to commercial cloud computing because the lower per-unit costs of a WSC meant that companies could rent servers at a profit below what it costs outsiders to do so themselves. The flip side of 100,000 servers is failures. [Figure 6.1](#) shows outages and anomalies for 2400 servers. Even if a server had a mean time to failure (MTTF) of an amazing 25 years (200,000 h), the WSC architect would need to design for five server failures a day. [Figure 6.1](#) lists the annualized disk failure rate as 2%–10%. Given two disks per server and an annual failure rate of 4%, with 100,000 servers the WSC architect should expect to see one disk fail per *hour*. However, software failures vastly outnumber hardware failures, as [Figure 6.1](#) shows, so the system design must be resilient to server crashes caused by software bugs, which would happen even more frequently than disk failures. With the thousands of servers in these very large facilities, WSC operators become very good at changing disks, so the cost of disk failure is much lower for a WSC than a small data center. The same applies to DRAMs. Plausibly, WSCs could use even less reliable components if cheaper ones were available.

Approx. number events in 1st year	Cause	Consequence
1 or 2	Power utility failures	Lose power to whole WSC; doesn't bring down WSC if UPS and generators work (generators work about 99% of time).
4	Cluster upgrades	Planned outage to upgrade infrastructure, many times for evolving networking needs such as recabling, to switch firmware upgrades, and so on. There are about nine planned cluster outages for every unplanned outage.
1000s	Hard-drive failures	2%–10% annual disk failure rate (Pinheiro et al., 2007)
	Slow disks	Still operate, but run 10× to 20× more slowly
	Bad memories	One uncorrectable DRAM error per year (Schroeder et al., 2009)
	Misconfigured machines	Configuration led to ~30% of service disruptions (Barroso and Hölzle, 2009)
	Flaky machines	1% of servers reboot more than once a week (Barroso and Hölzle, 2009)
5000	Individual server crashes	Machine reboot; typically takes about 5 min (caused by problems in software or hardware).

Figure 6.1 List of outages and anomalies with the approximate frequencies of occurrences in the first year of a new cluster of 2400 servers. We label what Google calls a cluster an *array*; see [Figure 6.5](#). Based on Barroso, L.A., 2010. Warehouse Scale Computing [keynote address]. In: Proceedings of ACM SIGMOD, June 8–10, 2010, Indianapolis, IN.

Example Calculate the availability of a service running on the 2400 servers in [Figure 6.1](#). Unlike a service in a real WSC, in this example the service cannot tolerate hardware or software failures. Assume that the time to reboot software is 5 min and the time to repair hardware is 1 h.

Answer We can estimate service availability by calculating the time of outages because of failures of each component. We'll conservatively take the lowest number in each category in [Figure 6.1](#) and split the 1000 outages evenly between four components. We ignore slow disks—the fifth component of the 1000 outages—because they hurt performance but not availability, and power utility failures, because the uninterruptible power supply (UPS) system hides 99% of them.

$$\begin{aligned}\text{Hours Outage}_{\text{service}} &= (4 + 250 + 250 + 250) \times 1 \text{ h} + (250 + 5000) \times 5 \text{ min} \\ &= 754 + 438 = 1192 \text{ h}\end{aligned}$$

Since there are 365×24 or 8760 h in a year, availability is

$$\text{Availability}_{\text{system}} = \left(\frac{8760 - 1192}{8760} \right) = \frac{7568}{8760} = 86\%$$

Without software redundancy to mask the many outages, a service on those 2400 servers would be down on average one day a week—zero “nines”—which is far below the 99.99% of availability is the goal of WSCs.

As [Section 6.10](#) explains, the forerunners of WSCs are *computer clusters*. Clusters are collections of independent computers that are connected together using local area networks (LANs) and switches. For workloads that did not require intensive communication, clusters offered much more cost-effective computing than shared-memory multiprocessors. (Shared-memory multiprocessors were the forerunners of the multicore computers discussed in [Chapter 5](#).) Clusters became popular in the late 1990s for scientific computing and then later for Internet services. One view of WSCs is that they are just the logical evolution from clusters of hundreds of servers to tens of thousands of servers.

A natural question is whether WSCs are similar to modern clusters for high-performance computing. Although some have similar scale and cost—there are HPC designs with a million processors that cost hundreds of millions of dollars—they historically have had more powerful processors and much lower-latency networks between the nodes than are found in WSCs because the HPC applications are more interdependent and communicate more frequently (see [Section 6.3](#)). The programming environment also emphasizes thread-level parallelism or data-level parallelism (see [Chapters 4 and 5](#)), typically emphasizing latency to complete a single task in contrast to bandwidth to complete many independent tasks via request-level parallelism. The HPC clusters also tend to have long-running jobs that keep the servers fully utilized, even for weeks at a time,

whereas the utilization of servers in WSCs ranges between 10% and 50% (see [Figure 6.3](#) on page 441) and varies every day. Unlike supercomputer environments, thousands of developers work on the WSC code base and deploy significant software releases every week ([Barroso et al., 2017](#)).

How do WSCs compare to conventional data centers? The operators of a traditional data center generally collect machines and third-party software from many parts of an organization and run them centrally for others. Their main focus tends to be consolidation of the many services onto fewer machines, which are isolated from each other to protect sensitive information. Thus, virtual machines are increasingly important in data centers. Virtual machines are important for WSCs as well, but they play a different role. They are used to offer isolation between different customers and to slice hardware resources into different-sized shares to rent at several price points (see [Section 6.5](#)). Unlike WSCs, conventional data centers tend to have a great deal of hardware and software heterogeneity to serve their varied customers inside an organization. WSC programmers customize third-party software or build their own, and WSCs have much more homogeneous hardware; the WSC goal is to make the hardware/software in the warehouse act like a single computer that typically runs a variety of applications. Often the biggest cost in a conventional data center is the people to maintain it, whereas, as we will see in [Section 6.4](#), in a well-designed WSC, the server hardware is the greatest cost, and people costs shift from the topmost to the bottommost. Conventional data centers also don't have the scale of a WSC, so they don't get the economic benefits of the scale previously mentioned.

Thus, although a WSC might be considered as an extreme data center in that computers are housed separately in a space with special electrical and cooling infrastructure, traditional data centers share little with the challenges and opportunities of a WSC, either architecturally or operationally.

We start the introduction to WSCs with their workload and a programming model.

6.2

Programming Models and Workloads for Warehouse-Scale Computers

If a problem has no solution, it may not be a problem, but a fact—not to be solved, but to be coped with over time.

Shimon Peres

In addition to the public-facing Internet services such as search, video sharing, and social networking that make them famous, WSCs also run batch applications, such as converting videos into new formats or creating search indexes from web crawls.

A popular framework for batch processing in a WSC is MapReduce ([Dean and Ghemawat, 2008](#)) and its open-source twin Hadoop. [Figure 6.2](#) shows the increasing popularity of MapReduce at Google over time. Inspired by the Lisp functions

Month	Number of MapReduce Jobs	Average completion time (s)	Average no. servers per job	Avg. no. cores per server	CPU core years	Input data (PB)	Intermediate data (PB)	Output data (PB)

Figure 6.2 Monthly MapReduce usage at Google from 2004 to 2016. Over 12 years the number of MapReduce jobs increased by a factor of 3300. [Figure 6.17](#) on page 461 estimates that running the September 2016 workload on Amazon’s cloud computing service EC2 would cost \$114 million. Updated from Dean, J., 2009. Designs, lessons and advice from building large distributed systems [keynote address]. In: Proceedings of 3rd ACM SIGOPS International Workshop on Large-Scale Distributed Systems and Middleware, Co-located with the 22nd ACM Symposium on Operating Systems Principles, October 11–14, 2009, Big Sky, Mont.

of the same name, Map first applies a programmer-supplied function to each logical input record. Map runs on hundreds of computers to produce an intermediate result of key-value pairs. Reduce collects the output of those distributed tasks and collapses them using another programmer-defined function. Assuming the Reduce function is commutative and associative, it can run in log N time. With appropriate software support, both functions are fast yet easy to understand and use. Within 30 min, a novice programmer can run a MapReduce task on thousands of computers.

[Figure 6.2](#) shows the average job uses hundreds of servers. Other than a few highly tuned applications from high-performance computing, such MapReduce jobs are the most parallel applications today, whether measured in total CPU time or number of servers utilized.

Here is a MapReduce program that calculates the number of occurrences of every English word in a large collection of documents. Following is a simplified version of that program, which shows just the inner loop and that assumes only one occurrence of all English words found in a document ([Dean and Ghemawat, 2008](#)):

```

map(String key, String value):
    // key: document name
    // value: document contents
    for each word w in value:
        EmitIntermediate(w, "1"); // Produce list of
                                   all words

reduce(String key, Iterator values):
    // key: a word
    // values: a list of counts
    int result = 0;
    for each v in values:
        result += ParseInt(v); // get integer from key-
                                value pair
    Emit(AsString(result));

```

The function `EmitIntermediate` used in the `Map` function emits each word in the document and the value one. Then the `Reduce` function sums all the values per word for each document using `ParseInt()` to get the number of occurrences per word in all documents. The MapReduce runtime environment schedules map tasks and reduce tasks to the nodes of a WSC. (The complete version of the program is found in [Dean and Ghemawat \(2008\)](#).)

MapReduce can be thought of as a generalization of the single instruction stream, multiple data streams (SIMD) operation ([Chapter 4](#))—except that a function to be applied is passed to the data—that is followed by a function that is used in a reduction of the output from the Map task. Because reductions are commonplace even in SIMD programs, SIMD hardware often offers special operations for the reductions. For example, Intel’s AVX SIMD instructions include “horizontal” instructions that add pairs of operands that are adjacent in registers.

To accommodate variability in performance from hundreds of computers, the MapReduce scheduler assigns new tasks based on how quickly nodes complete prior tasks. Obviously, a single slow task can hold up completion of a large MapReduce job. [Dean and Barroso \(2013\)](#) label such a situation *tail latency*. In a WSC, the solution to slow tasks is to provide software mechanisms to cope with such variability that is inherent at this scale. This approach is in sharp contrast to the solution for a server in a conventional data center, where traditionally slow tasks mean hardware is broken and needs to be replaced or that server software needs tuning and rewriting. Performance heterogeneity is the norm for 50,000–100,000 servers in a WSC. For example, toward the end of a MapReduce program, the system will start backup executions on other nodes of the tasks that haven’t completed yet and take the result from whichever finishes first. In return for increasing resource usage a few percentage points, [Dean and Ghemawat \(2008\)](#) found that some large tasks completed 30% faster.

Dependability was built into MapReduce from the start. For example, each node in a MapReduce job is required to report back to the master node periodically

with a list of completed tasks and with updated status. If a node does not report back by the deadline, the master node deems the node dead and reassigns the node's work to other nodes. Given the amount of equipment in a WSC, it's not surprising that failures are commonplace, as the prior example attests. To deliver on 99.99% availability, systems software must cope with this reality in a WSC. To reduce operational costs, all WSCs use automated monitoring software allowing one operator to be responsible for more than 1000 servers.

Programming frameworks such as MapReduce for batch processing and externally facing SaaS such as Search rely upon internal software services for their success. For example, MapReduce relies on the Google File System (GFS) (Ghemawat et al., 2003) or on Colossus (Fikes, 2010) to supply files to any computer, so that MapReduce tasks can be scheduled anywhere.

In addition to GFS and Colossus, examples of these scalable storage systems include Amazon's key value storage system Dynamo (DeCandia et al., 2007) and the Google record storage system BigTable (Chang et al., 2006). Note that such systems often build upon each other. For example, BigTable stores its logs and data on GFS or Colossus, much as a relational database may use the file system provided by the kernel operating system.

These internal services usually make different decisions than similar software running on single servers. For example, rather than assuming storage is reliable, such as by using RAID storage servers, these systems often make complete replicas of the data. Replicas can help with read performance as well as with availability; with proper placement, replicas can overcome many other system failures, like those in Figure 6.1. Systems like Colossus use error-correcting codes rather than full replicas to reduce storage costs, but the constant is cross-server redundancy rather than within-a-server or within-a-storage array redundancy. Thus, failure of the entire server or storage device doesn't negatively affect availability of the data.

Another example of the different approach is that WSC storage software often uses relaxed consistency rather than following all the ACID (atomicity, consistency, isolation, and durability) requirements of conventional database systems. The insight is that it's important for multiple replicas of data to agree *some time*, but, for most applications, they do not need to be in agreement at all times. For example, eventual consistency is fine for video sharing. Eventual consistency makes storage systems much easier to scale, which is an absolute requirement for WSCs.

The workload demands of these public interactive services all vary considerably; even a prominent global service such as Google Search varies by a factor of two depending on the time of day. When factoring in weekends, holidays, and popular times of year for some applications—such as photograph-sharing services after New Year's Day or online shopping before Christmas—a much greater variation in server utilization becomes apparent. Figure 6.3 shows average utilization of 5000 Google servers over a 6-month period. Note that less than 0.5% of servers averaged 100% utilization, and most servers operated between 10% and 50% utilization. Stated alternatively, just 10% of all servers were utilized more than 50%. Thus, it's much more important for servers in a WSC to perform

Figure 6.3 Average CPU utilization of more than 5000 servers during a 6-month period at Google. Servers are rarely completely idle or fully utilized, instead operating most of the time at between 10% and 50% of their maximum utilization. The third column from the right in [Figure 6.4](#) calculates percentages plus or minus 5% to come up with the weightings; thus 1.2% for the 90% row means that 1.2% of servers were between 85% and 95% utilized. From Figure 1 in Barroso, L.A., Hölzle, U., 2007. The case for energy-proportional computing. *IEEE Comput.* 40 (12), 33–37.

well while doing little than to perform efficiently only at their peak, as they rarely operate at their peak.

In summary, WSC hardware and software must cope with variability in load based on user demand and in performance and dependability because of the vagaries of hardware at this scale.

Example As a result of measurements like those in [Figure 6.3](#), the SPECpower benchmark measures power and performance from 0% load to 100% in 10% increments (see [Chapter 1](#)). The overall single metric that summarizes this benchmark is the sum of all the performance measures (server-side Java operations per second) divided by the sum of all power measurements in watts. Thus, each level is assumed to be equally likely. How would the numbers summary metric change if the levels were weighted by the utilization frequencies in [Figure 6.3](#)?

Load	Performance	Watts	SPEC weightings	Weighted performance	Weighted watts	Figure 6.3 weightings	Weighted performance	Weighted watts
100%	2,889,020	662	9.09%	262,638	60	0.80%	22,206	5

Figure 6.4 SPECpower result using the weightings from Figure 6.3 instead of even weightings.

Answer Figure 6.4 shows the original weightings and the new weighting that match Figure 6.3. These weightings reduce the performance summary by 30% from 3210 ssj_ops/watt to 2454.

Given the scale, software must handle failures, which means there is little reason to buy “gold-plated” hardware that reduces the frequency of failures. The primary impact would be to increase cost. Barroso and Hölzle (2009) found a factor of 20 difference in price-performance between a high-end Hewlett Packard shared-memory multiprocessor and a commodity Hewlett Packard server when running the TPC-C database benchmark. Not surprisingly, Google and all other companies with WSCs use low-end commodity servers. In fact, the Open Compute Project (<http://opencompute.org>) is an organization where such companies collaborate on open designs of servers and racks for data centers.

Such WSC services also tend to develop their own software rather than buy third-party commercial software, in part to cope with the huge scale and in part to save money. For example, even on the best price-performance platform for TPC-C in 2017, adding the cost of the SAP SQL Anywhere database and the Windows operating system increases the cost of the Dell PowerEdge T620 server by 40%. In contrast, Google runs BigTable and the Linux operating system on its servers, for which it pays no licensing fees.

Given this review of the applications and systems software of a WSC, we are ready to look at the computer architecture of a WSC.

6.3

Computer Architecture of Warehouse-Scale Computers

Networks are the connective tissue that binds 50,000–100,000 servers together. Analogous to the memory hierarchy of [Chapter 2](#), WSCs use a hierarchy of networks. [Figure 6.5](#) shows one example. Ideally, the combined network would provide nearly the performance of a custom high-end switch for 100,000 servers at about the cost per port of a commodity switch designed for 50 servers. As we will see in [Section 6.6](#), networks for WSCs are an area of active innovation.

The structure that holds the servers is a rack. Although the width of racks varies per WSC—some are the classic 19-in. wide rack; others are two or three times wider—the height tends to be no higher than 6–7 ft since people must service them. Such a rack has roughly 40–80 servers. Because it is often convenient to connect the network cables at the top of the rack, this switch is commonly called a *Top of Rack (ToR)* switch. (Some WSCs have racks with multiple ToR switches.) Typically, the bandwidth within the rack is much higher than between racks,

Figure 6.5 Hierarchy of switches in a WSC. Based on Figure 1.1 in Barroso, L.A., Clidaras, J., Hölzle, U., 2013. The datacenter as a computer: an introduction to the design of warehouse-scale machines. *Synth. Lect. Comput. Architect.* 8 (3), 1–154.

so it matters less where the software places the sender and the receiver if they are within the same rack. This flexibility is ideal from a software perspective.

These switches often offer 4–16 uplinks, which leave the rack to go to the next higher switch in the network hierarchy. Thus, the bandwidth leaving the rack is 6–24 times smaller than the bandwidth within the rack. This ratio is called *oversubscription*. However, large oversubscription means programmers must be aware of the performance consequences when placing senders and receivers in different racks. This increased software-scheduling burden is another argument for network switches designed specifically for the data center.

The switch that connects an array of racks is considerably more expensive than the ToR switch. This cost is due in part because of the higher connectivity and in part because the bandwidth through the switch must be much greater to reduce the oversubscription problem. Barroso et al. (2013) reported that a switch having 10 times the *bisection bandwidth*—basically, the worst-case internal bandwidth—of a rack switch costs about 100 times as much. One reason is that the cost of switch bandwidth for n ports can grow as n^2 . Sections 6.6 and 6.7 describe the networking above the ToR switch in great detail.

Storage

A natural design is to fill a rack with servers, minus whatever space needed for the switches. This design leaves open the question of where the storage is placed. From a hardware construction perspective, the simplest solution would be to include disks inside the rack and rely on Ethernet connectivity for access to information on the disks of remote servers. An expensive alternative would be to use network-attached storage (NAS), perhaps over a storage network like InfiniBand. In the past, WSCs generally relied on local disks and provided storage software that handled connectivity and dependability. For example, GFS used local disks and maintained replicas to overcome dependability problems. This redundancy covered not only local disk failures but also power failures to racks and to whole clusters. The flexibility of GFS’s eventual consistency lowers the cost of keeping replicas consistent, which also reduces the network bandwidth requirements of the storage system.

Today the storage options are considerably more varied. Although some racks are balanced in terms of servers and disks, as in the past, there may also be racks deployed without local disks and some racks loaded with disks. System software today often uses RAID-like error correction codes to lower the storage cost of dependability.

Be aware that there is confusion about the term *cluster* when talking about the architecture of a WSC. Using the definition in Section 6.1, a WSC is just an extremely large cluster. In contrast, Barroso et al. (2013) used the term *cluster* to mean the next-sized grouping of computers, containing many racks. In this chapter, to avoid confusion, we will use the term *array* to mean a large collection of racks organized in rows, preserving the original definition of the word *cluster* to represent anything from a collection of networked computers within a rack to an entire warehouse full of networked computers.

WSC Memory Hierarchy

Figure 6.6 shows the latency, bandwidth, and capacity of memory hierarchy inside a WSC, and Figure 6.7 shows the same data visually. These figures are based on the following assumptions (Barroso et al., 2013):

	Local	Rack	Array
DRAM latency (μ s)	0.1	300	500
Flash latency (μ s)	100	400	600
Disk latency (μ s)	10,000	11,000	12,000
DRAM bandwidth (MB/s)	20,000	100	10
Flash bandwidth (MB/s)	1000	100	10
Disk bandwidth (MB/s)	200	100	10
DRAM capacity (GB)	16	1024	31,200
Flash capacity (GB)	128	20,000	600,000
Disk capacity (GB)	2000	160,000	4,800,000

Figure 6.6 Latency, bandwidth, and capacity of the memory hierarchy of a WSC (Barroso et al., 2013). Figure 6.7 plots this same information.

Figure 6.7 Graph of latency, bandwidth, and capacity of the memory hierarchy of a WSC for data in Figure 6.6 (Barroso et al., 2013).

- Each server contains 16 GiB of memory with a 100-ns access time and transfers at 20 GB/s, 128 GiB of Flash with 100-μs latency and transfers at 1 GB/s, and 2 TB of disk that offer a 10-ms access time and transfer at 200 MB/s. There are two sockets per board, and they share one 1 Gbit/s Ethernet port.
- In this example, every pair of racks includes one rack switch and holds 80 servers. Networking software plus switch overhead increases the latency to DRAM to 100 μs and the disk access latency to 11 ms. Thus, the total storage capacity of a rack is roughly 1 TB of DRAM, 20 TB of Flash, and 160 TB of disk storage. The 1 Gbit/s Ethernet limits the remote bandwidth to DRAM, Flash, or disk within the rack to 100 MB/s.
- The array is 30 racks, so storage capacity of an array goes up by a factor of 30: 30 TB of DRAM, 600 TB of Flash, and 4.8 PB of disk. The array switch hardware and software increases latency to DRAM within an array to 500 μs, to 600 μs for Flash, and disk latency to 12 ms. The bandwidth of the array switch limits the remote bandwidth to either array DRAM, array Flash, or array disk to 10 MB/s.

Figures 6.6 and 6.7 show that network overhead dramatically increases latency between local DRAM and Flash, rack DRAM and Flash, or array DRAM and Flash, but all still have more than 10 times better latency than accessing the local disk. The network collapses the difference in bandwidth between rack DRAM, Flash, and disk and between array DRAM, Flash, and disk.

The WSC needs 40 arrays to reach 100,000 servers, so there is one more level in the networking hierarchy. Figure 6.8 shows the conventional Layer 3 routers to connect the arrays together and to the Internet.

Most applications fit into a single array within a WSC. Those that need more than one array use *sharding* or *partitioning*, meaning that the dataset is split into independent pieces and then distributed to different arrays. As an analogy, it's like picking up registration packets for a conference with one person handling names A to M and another doing N to Z. Operations on the whole dataset are sent to the servers hosting the pieces, and the results are coalesced by the client computer.

Example What is the average memory latency assuming that 90% of accesses are local to the server, 9% are outside the server but within the rack, and 1% are outside the rack but within the array?

Answer The average memory access time is

$$(90\% \times 0.1) + (9\% \times 100) + (1\% \times 300) = 0.09 + 27 + 5 = 32.09 \mu\text{s}$$

or a factor of more than 300 slowdown versus 100% local accesses. Clearly, locality of access within a server is vital for WSC performance.

Example How long does it take to transfer 1000 MB between disks within the server, between servers in the rack, and between servers in different racks in the array? How much faster is it to transfer 1000 MB between DRAM in the three cases?

Answer A 1000 MB transfer between disks takes

$$\text{Within server} = 1000/200 = 5 \text{ s}$$

$$\text{Within rack} = 1000/100 = 10 \text{ s}$$

$$\text{Within array} = 1000/10 = 100 \text{ s}$$

A memory-to-memory block transfer takes

$$\text{Within server} = 1000/20000 = 0.05 \text{ s}$$

$$\text{Within rack} = 1000/100 = 10 \text{ s}$$

$$\text{Within array} = 1000/10 = 100 \text{ s}$$

Thus, for block transfers outside a single server, it doesn't even matter whether the data are in memory or on disk because the rack switch and array switch are the bottlenecks. These performance limits affect the design of WSC software and inspire the need for higher-performance switches (see [Section 6.6](#)).

Figure 6.8 A Layer 3 network used to link arrays together and to the Internet (Greenberg et al., 2009). A load balancer monitors how busy a set of servers is and directs traffic to the less loaded ones to try to keep the servers approximately equally utilized. Another option is to use a separate *border router* to connect the Internet to the data center Layer 3 switches. As we will see in [Section 6.6](#), many modern WSCs have abandoned the conventional layered networking stack of traditional switches.

Although these examples are educational, note that computers and networking equipment can be much larger and faster than these examples from 2013 (see [Section 6.7](#)). Servers are being deployed in 2017 with 256–1024 GiB of DRAM, and recent switches have reduced delays to only 300 ns per hop.

Given the architecture of the IT equipment, we are now ready to see how to house, power, and cool it and to discuss the cost to build and operate the whole WSC, as compared to just the IT equipment within it.

6.4

The Efficiency and Cost of Warehouse-Scale Computers

Infrastructure costs for power distribution and cooling are the majority of the construction costs of a WSC, so we concentrate on them. ([Section 6.7](#) describes the power and cooling infrastructure of a WSC in detail.)

A *computer room air-conditioning (CRAC)* unit cools the air in the server room using chilled water, similar to how a refrigerator removes heat by releasing it outside the refrigerator. As a liquid absorbs heat, it evaporates. Conversely, when a liquid releases heat, it condenses. Air conditioners pump the liquid into coils under low pressure to evaporate and absorb heat, which is then sent to an external condenser where it is released. Thus, in a CRAC unit, fans push warm air past a set of coils filled with cold water, and a pump moves the warmed water to the chillers to be cooled down. [Figure 6.9](#) shows the large collection of fans and water pumps that move air and water throughout the system.

In addition to chillers, some data centers leverage colder outside air or water temperature to cool the water before it is sent to the chillers. However, depending on the location, the chillers may still be needed during the warmer times of the year.

Surprisingly, it's not obvious how to figure out how many servers a WSC can support after subtracting the overhead for power distribution and cooling. The *nameplate power rating* from the server manufacturer is always conservative: it's the maximum power a server can draw. The first step then is to measure a single server under a variety of workloads to be deployed in the WSC. (Networking is typically about 5% of power consumption, so it can be ignored at first.)

To determine the number of servers for a WSC, the available power for IT equipment could be divided just by the measured server power; however, this would again be too conservative according to [Fan et al. \(2007\)](#). They found that there is a significant gap between what thousands of servers could theoretically do, in the worst case, and what they will do in practice, since no real workloads will keep thousands of servers all simultaneously at their peaks. They found that they could safely oversubscribe the number of servers by as much as 40% based on the power of a single server. They recommended that WSC architects should do so to increase the average utilization of power within a WSC; however, they also suggested using extensive monitoring software along with a safety mechanism that de-schedules lower priority tasks in case the workload shifts.

Here is the power usage inside the IT equipment for a Google WSC deployed in 2012 ([Barroso et al., 2013](#)):

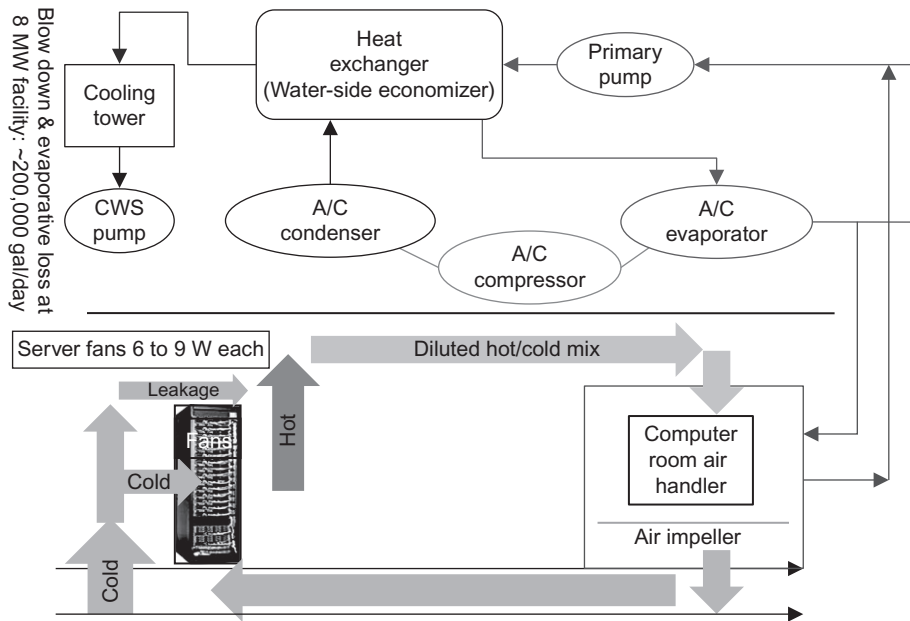

Figure 6.9 Mechanical design for cooling systems. CWS stands for circulating water system. From Hamilton, J., 2010. Cloud computing economies of scale. In: Paper Presented at the AWS Workshop on Genomics and Cloud Computing, June 8, 2010, Seattle, WA. http://mvdirona.com/jrh/TalksAndPapers/JamesHamilton_GenomicsCloud20100608.pdf.

- 42% of power for processors
- 12% for DRAM
- 14% for disks
- 5% for networking
- 15% for cooling overhead
- 8% for power overhead
- 4% miscellaneous

Measuring Efficiency of a WSC

A widely used, simple metric to evaluate the efficiency of a data center or a WSC is called *power utilization effectiveness* (or *PUE*):

$$\text{PUE} = (\text{Total facility power}) / (\text{IT equipment power})$$

Thus, PUE must be greater than or equal to 1, and the bigger the PUE, the less efficient the WSC.

Figure 6.10 Power utilization efficiency of 19 data centers in 2006 (Greenberg et al., 2009). The power for air conditioning (AC) and other uses (such as power distribution) is normalized to the power for the IT equipment in calculating the PUE. Thus, power for IT equipment must be 1.0, and AC varies from about 0.30 to 1.40 times the power of the IT equipment. Power for “other” varies from about 0.05 to 0.60 of the IT equipment.

Greenberg et al. (2009) reported on the PUE of 19 data centers and the portion of the overhead that went into the cooling infrastructure. Figure 6.10 shows what they found, sorted by PUE from most to least efficient. The median PUE is 1.69, with the cooling infrastructure using more than half as much power as the servers—on average, 0.55 of the 1.69 is for cooling. Note that these are average PUEs, which can vary daily depending on workload and even external air temperature, as we will see (Figure 6.11).

With attention paid to PUE in the past decade, data centers are much more efficient today. However, as Section 6.8 explains, there is no universally accepted definition of what is included in PUE: If the batteries to preserve operation during a power failure are in a separate building, are they included or not? Do you measure from the output of the power substation, or where power first enters the WSC? Figure 6.10 shows the improvement in the average PUE of all Google data centers over time, which Google measures inclusively.

Since performance per dollar is the ultimate metric, we still need to measure performance. As Figure 6.7 shows, bandwidth drops and latency increases depending on the distance to the data. In a WSC, the DRAM bandwidth within a server is 200 times greater than within a rack, which in turn is 10 times greater than within an array. Thus, there is another kind of locality to consider in the placement of data and programs within a WSC.

Figure 6.11 Average power utilization efficiency (PUE) of the 15 Google WSCs between 2008 and 2017. The spiking line is the quarterly average PUE, and the straighter line is the trailing 12-month average PUE. For Q4 2016, the averages were 1.11 and 1.12, respectively.

Although designers of a WSC often focus on bandwidth, programmers developing applications on a WSC are also concerned with latency because latency is visible to users. Users' satisfaction and productivity are tied to response time of a service. Several studies from the timesharing days report that user productivity is inversely proportional to time for an interaction, which was typically broken down into human entry time, system response time, and time for the person to think about the response before hitting the next entry (Doherty and Thadhani, 1982). The results of experiments showed that cutting system response time by 30% shaved the time of an interaction by 70% (Brady, 1986). This implausible result is explained by human nature: people need less time to think when given a faster response, as they are less likely to get distracted and remain “on a roll.”

Figure 6.12 shows the results of a more recent experiment for the Bing search engine, where delays of 50–2000 ms were inserted at the search server (Schurman and Brutlag, 2009). As expected from previous studies, time to next click roughly doubled the delay; that is, a 200 ms delay at the server led to a 500 ms increase in time to next click. Revenue dropped linearly with increasing delay, as did user satisfaction. A separate study on the Google search engine found that these effects lingered long after the 4-week experiment ended. Five weeks later, there were 0.1% fewer searchers per day for users who experienced 200 ms delays, and there were 0.2% fewer searches by users who experienced 400 ms delays. Given the amount of money made in search, even such small changes are disconcerting. In fact, the results were so negative that they ended the experiment prematurely.

Because of this extreme concern with satisfaction of all users of an Internet service, performance goals are typically specified so that a high percentage of requests are below a latency threshold, rather than just offer a target for the average latency. Such threshold goals are called *service level objectives* (SLOs). An SLO might be that 99% of requests must be below 100 ms. Thus, the designers of

Server delay (ms)	Increased time to next click (ms)	Queries/user	Any clicks/user	User satisfaction	Revenue/user
50	—	—	—	—	—
200	500	—	−0.3%	−0.4%	—
500	1200	—	−1.0%	−0.9%	−1.2%
1000	1900	−0.7%	−1.9%	−1.6%	−2.8%
2000	3100	−1.8%	−4.4%	−3.8%	−4.3%

Figure 6.12 Negative impact of delays at the Bing search server on user behavior (Schurman and Brutlag, 2009).

Amazon's Dynamo key-value storage system decided that for services to offer good latency on top of Dynamo, their storage system had to deliver on its latency goal 99.9% of the time (DeCandia et al., 2007). For example, one improvement of Dynamo helped the 99.9th percentile much more than the average case, which reflects their priorities.

Dean and Barroso (2013) proposed the term *tail tolerant* to describe systems designed to meet such goals:

Just as fault-tolerant computing aims to create a reliable whole out of less-reliable parts, large online services need to create a predictably responsive whole out of less-predictable parts.

The causes of unpredictability include contention for shared resources (processors networks, etc.), queuing, variable microprocessor performance because of optimizations like Turbo mode or energy-saving techniques like DVFS, software garbage collection, and many more. Google concluded that instead of trying to prevent such variability in a WSC, it made more sense to develop tail-tolerant techniques to mask or work around temporary latency spikes. For example, fine-grained load balancing can quickly move small amounts for work between servers to reduce queuing delays.

Cost of a WSC

As mentioned in the introduction, unlike most architects, designers of WSCs worry about the cost to operate as well as the cost to build the WSC. Accounting labels the former costs as *operational expenditures* (OPEX) and the latter costs as *capital expenditures* (CAPEX).

To put the cost of energy into perspective, Hamilton (2010) did a case study to estimate the costs of a WSC. He determined that the CAPEX of an 8-MW facility was \$88 million and that the roughly 46,000 servers and corresponding networking equipment added another \$79 million to the CAPEX for the WSC. Figure 6.13 shows the rest of the assumptions for the case study.

Size of facility (critical load watts)	8,000,000
Average power usage (%)	80%
Power usage effectiveness	1.45
Cost of power (\$/kWh)	\$0.07
% Power and cooling infrastructure (% of total facility cost)	82%
CAPEX for facility (not including IT equipment)	\$88,000,000
Number of servers	45,978
Cost/server	\$1450
CAPEX for servers	\$66,700,000
Number of rack switches	1150
Cost/rack switch	\$4800
Number of array switches	22
Cost/array switch	\$300,000
Number of layer 3 switches	2
Cost/layer 3 switch	\$500,000
Number of border routers	2
Cost/border router	\$144,800
CAPEX for networking gear	\$12,810,000
Total CAPEX for WSC	\$167,510,000
Server amortization time	3 years
Networking amortization time	4 years
Facilities amortization time	10 years
Annual cost of money	5%

Figure 6.13 Case study for a WSC, rounded to nearest \$5000. Internet bandwidth costs vary by application, so they are not included here. The remaining 18% of the CAPEX for the facility includes buying the property and the cost of construction of the building. We added people costs for security and facilities management in Figure 6.14, which were not part of the case study. Note that Hamilton's estimates were done before he joined Amazon, and they are not based on the WSC of a particular company. Based on Hamilton, J., 2010. Cloud computing economies of scale. In: Paper Presented at the AWS Workshop on Genomics and Cloud Computing, June 8, 2010, Seattle, WA. http://mvdirona.com/jrh/TalksAndPapers/JamesHamilton_GenomicsCloud20100608.pdf.

Hamilton's study works out to \$11/watt for the building, power, and cooling. Barroso et al. (2013) reported consistent results for several cases, with the cost at \$9 to \$13/watt. Thus, a 16-MW facility costs \$144 million to \$208 million, *not* including the computing, storage, and networking equipment.

We can convert CAPEX into OPEX by a cost of capital conversion, assuming 5% borrowing cost, which is a standard convention in US accounting rules. That is, we can just amortize CAPEX as a fixed amount each month for the effective life of

the equipment. Figure 6.14 breaks down the monthly OPEX for Hamilton’s case study. Note that the amortization rates differ significantly for his case study, from 10 years for the facility to 4 years for the networking equipment and 3 years for the servers. Thus, the WSC facility lasts a decade, but the servers are replaced every 3 years and the networking equipment every 4 years. By amortizing the CAPEX, Hamilton came up with a monthly OPEX, including accounting for the cost of borrowing money (5% annually) to pay for the WSC. At \$3.8 million, the monthly OPEX is about 2% of the CAPEX (or 24% annually).

This figure allows us to calculate a handy guideline to keep in mind when making decisions about which components to use when being concerned about energy. The fully burdened cost of a watt per year in a WSC, including the cost of amortizing the power and cooling infrastructure, is

$$\frac{\text{Monthly cost of infrastructure} + \text{monthly cost of power}}{\text{Facility size in watts}} \times 12 = \frac{\$765\text{K} + \$475\text{K}}{8\text{M}} \times 12 = \$1.86$$

The cost is roughly \$2 per watt-year. Thus, reducing costs by saving energy should not result in spending more than \$2 per watt-year (see Section 6.8).

Note that in Figure 6.14, more than a third of OPEX is related to power, with that category trending up while server costs are trending down over time. The networking equipment is significant at 8% of total OPEX and 19% of the server CAPEX, and networking equipment is not trending down as quickly as servers are, perhaps because of the continuing demand for higher network bandwidth (see Figure 6.22 on page 467). This difference is especially true for the switches in the networking hierarchy above the rack, which represent most of the networking costs (see Section 6.6). People costs for security and facilities management are just 2% of OPEX. Dividing the OPEX in Figure 6.14 by the number of servers and hours per month, the cost is about \$0.11 per server per hour.

Expense (% total)	Category	Monthly cost	Percent monthly cost
Amortized CAPEX (85%)	Servers	\$2,000,000	53%
	Networking equipment	\$290,000	8%
	Power and cooling infrastructure	\$765,000	20%
	Other infrastructure	\$170,000	4%
OPEX (15%)	Monthly power use	\$475,000	13%
	Monthly people salaries and benefits	\$85,000	2%
	Total OPEX	\$3,800,000	100%

Figure 6.14 Monthly OPEX for Figure 6.13, rounded to the nearest \$5000. Note that the 3-year amortization of servers means purchasing new servers every 3 years, whereas the facility is amortized for 10 years. Thus, the amortized capital costs for servers are about three times more than for the facility. People costs include three security guard positions continuously for 24 h a day, 365 days a year, at \$20 per hour per person, and one facilities person for 24 h a day, 365 days a year, at \$30 per hour. Benefits are 30% of salaries. This calculation does not include the cost of network bandwidth to the Internet because it varies by application nor vendor maintenance fees because they vary by equipment and by negotiations.

Barroso et al. (2013) evaluated CAPEX and OPEX in terms of cost per watt per month. Thus, if a 12-MW WSC is depreciated over 12 years, the depreciation cost is \$0.08 per watt per month. They assumed the company got the capital for the WSC by taking out a loan at 8% annually—corporate loans are typically between 7% and 12%—and the interest payments added another \$0.05, giving a total of \$0.13 per watt per month. They factored in the cost of servers similarly. A 500 watt server that cost \$4000 was \$8 per watt, and the 4-year depreciation was \$0.17 per watt per month. An 8% interest on a loan for the servers added \$0.02. They estimated networking at \$0.03 per watt per month. They reported that the typical OPEX cost for multiple MW WSCs varied from \$0.02 to \$0.08 per watt per month. The grand total was \$0.37 to \$0.43 per watt per month. For an 8-MW WSC, the monthly cost minus the cost of electricity is about \$3.0 million to \$3.5 million. If we subtract the monthly power use from Hamilton’s calculation, his estimate of the monthly rate will be \$3.3 million. Given the different approaches to predicting costs, these estimates are remarkably consistent.

Example The cost of electricity varies by region in the United States from \$0.03 to \$0.15 per kilowatt-hour. What is the impact on hourly server costs of these two extreme rates?

Answer We multiply the critical load of 8 MW by the average PUE from Figure 6.13 (second row) to calculate the average power usage:

$$8 \times 1.45 \times 80\% = 9.28 \text{ Megawatts}$$

The monthly cost for power then goes from \$475,000 in Figure 6.14 to \$205,000 at \$0.03 per kilowatt-hour and to \$1,015,000 at \$0.15 per kilowatt-hour. These changes in electricity cost alter the hourly server costs from \$0.11 to \$0.10 and \$0.13, respectively.

Example What would happen to monthly costs if the amortization times were all made to be the same—say, 5 years? How would that change the hourly cost per server?

Answer The spreadsheet is available online at <http://mvdirona.com/jrh/TalksAndPapers/PerspectivesDataCenterCostAndPower.xls>. Changing the amortization time to 5 years changes the first four rows of Figure 6.14 to

Servers	\$1,260,000	37%
Networking equipment	\$242,000	7%
Power and cooling infrastructure	\$1,115,000	33%
Other infrastructure	\$245,000	7%

and the total monthly OPEX is \$3,422,000. If we replaced everything every 5 years, the cost would be \$0.103 per server hour, with more of the amortized costs now being for the facility rather than the servers, as in Figure 6.14.

The rate of about \$0.10 per server per hour can be much less than the cost for many companies that own and operate their own (smaller) conventional data centers. The cost advantage of WSCs led large Internet companies to offer computing as a utility where, like electricity, you pay only for what you use. Today, utility computing is better known as *cloud computing*.

6.5

Cloud Computing: The Return of Utility Computing

If computers of the kind I have advocated become the computers of the future, then computing may someday be organized as a public utility just as the telephone system is a public utility.... The computer utility could become the basis of a new and important industry.

John McCarthy,

MIT centennial celebration (1961)

Driven by the demand of an increasing number of users, Internet companies such as Amazon, Google, and Microsoft built increasingly larger warehouse-scale computers from commodity components, making McCarthy's prediction eventually come true, but not as he thought because of the popularity of timesharing. This demand led to innovations in systems software to support operating at this scale, including BigTable, Colossus, Dynamo, GFS, and MapReduce. It also demanded improvement in operational techniques to deliver a service available at least 99.99% of the time despite component failures and security attacks. Examples of these techniques include failover, firewalls, virtual machines, and protection against distributed denial-of-service attacks. With the software and expertise providing the ability to scale and increasing customer demand that justified the investment, WSCs with 50,000–100,000 servers have become commonplace in 2017.

With increasing scale came increasing economies of scale. Based on a study in 2006 that compared a WSC with a data center with only 1000 servers, [Hamilton \(2010\)](#) reported the following advantages:

- *5.7 times reduction in storage costs*—It cost the WSC \$4.6 per GB per year for disk storage versus \$26 per GB for the data center.
- *7.1 times reduction in administrative costs*—The ratio of servers per administrator was over 1000 for the WSC versus just 140 for the data center.
- *7.3 times reduction in networking costs*—Internet bandwidth cost the WSC \$13 per Mbit/s/month versus \$95 for the data center. Not surprisingly, one can negotiate a much better price per Mbit/s by ordering 1000 Mbit/s than by ordering 10 Mbit/s.

Another economy of scale comes during purchasing. The high level of purchasing leads to volume discount prices on virtually everything in the WSC.

Economies of scale also apply to operational costs. From the prior section, we saw that many data centers operate with a PUE of 2.0. Large firms can justify hiring mechanical and power engineers to develop WSCs with lower PUEs, in the range of 1.1–1.2 (see [Section 6.7](#)).

Internet services need to be distributed to multiple WSCs both for dependability and to reduce latency, especially for international markets. All large firms use multiple WSCs for that reason. It's much more expensive for individual firms to create multiple, small data centers around the world than a single data center in their corporate headquarters.

Finally, for the reasons presented in [Section 6.1](#), servers in data centers tend to be utilized only 10%–20% of the time. By making WSCs available to the public, uncorrelated peaks between different customers can raise average utilization above 50%.

Thus, economies of scale for a WSC offer factors of 5–7 for several components of a WSC plus a few factors of 1.5–2 for the entire WSC.

Since the last edition of this book, the concerns about security have flipped for the cloud. In 2011 there was skepticism about placing critical data in the cloud because that could make it easier for hackers to break into than if the data were kept on premises (“on prem”) locked down in the local data center. In 2017 data break-ins into such data centers are so routine that they barely make the news.

For example, this insecurity has even led to rapid growth of *ransomware*—where criminals break in, encrypt all the data of an organization, and won't release the key until paid a ransom—costing firms \$1 billion in 2015. In contrast, WSCs are continuously under attack, their operators respond more quickly to halt them and thus build better defenses. As a result, ransomware is unheard of inside WSCs. WSCs are clearly more secure than the vast majority of local data centers today, so many CIOs now believe that critical data is safer in the cloud than “on prem.”

Although there are several cloud computing providers, we feature Amazon Web Services (AWS) since it is one of the oldest and currently the largest commercial cloud provider.

Amazon Web Services

Utility computing goes back to commercial timesharing systems and even batch processing systems of the 1960s and 1970s, where companies only paid for a terminal and a phone line and then were billed based on how much computing they used. Many efforts since the end of timesharing have tried to offer such pay-as-you-go services, but they were often met with failure.

When Amazon started offering utility computing via the Amazon Simple Storage Service (Amazon S3) and then Amazon Elastic Computer Cloud (Amazon EC2) in 2006, it made some novel technical and business decisions:

- *Virtual machines.* Building the WSC using x86-commodity computers running the Linux operating system and the Xen virtual machine solved several

problems. First, it allowed Amazon to protect users from each other. Second, it simplified software distribution within a WSC, in that customers needed to install only an image and then AWS automatically distributed it to all the instances being used. Third, the ability to kill a virtual machine reliably made it easy for Amazon and customers to control resource usage. Fourth, virtual machines could limit the rate at which they used the physical processors, disks, and the network as well as the amount of main memory, which gave AWS multiple price points: the lowest price option by packing many virtual cores on a single server, the highest price option of exclusive access to all the machine resources, as well as several intermediary points. Fifth, virtual machines hid the identity of hardware, allowing AWS to continue to sell time on older machines that might otherwise be unattractive to customers if they knew the age of the machines. Finally, virtual machines allowed AWS to introduce new and faster hardware either by packing even more virtual cores per server or simply by offering instances that had higher performance per virtual core; virtualization meant that offered performance need not be an integer multiple of the performance of the hardware.

- *Very low cost.* When AWS announced a rate of \$0.10 per hour per instance in 2006, it was a startlingly low amount. An instance is one virtual machine, and at \$0.10 per hour, AWS allocated two instances per core on a multicore server. Thus, one EC2 computer unit is equivalent to a 1.0–1.2 GHz AMD Opteron or Intel Xeon of that era.
- *(Initial) reliance on open source software.* The availability of good-quality software that had no licensing problems or costs associated with running on hundreds or thousands of servers made utility computing much more economical for both Amazon and its customers. AWS later started offering instances including commercial third-party software at higher prices.
- *No (initial) guarantee of service.* Amazon originally promised only best effort. The low cost was so attractive that many could live without a service guarantee. Today AWS provides availability SLOs of up to 99.95% on services such as Amazon EC2 and Amazon S3. Additionally, Amazon S3 was designed for durability by saving multiple replicas of each object across multiple locations. (According to AWS, the chances of permanently losing an object are one in 100 billion.) AWS also provides a Service Health Dashboard that shows the current operational status of each of the AWS services in real time so that AWS uptime and performance are fully transparent.
- *No contract required.* In part because the costs are so low, all that is necessary to start using EC2 is a credit card.

Figures 6.15 and 6.16 show the hourly price of the many types of EC2 instances in 2017. Expanding from the 10 instance types in 2006, there are now more than 50. The fastest instance is 100 times quicker than the slowest, and

	Instance	Per hour	Ratio to m4.large	Virtual cores	Compute units	Memory (GiB)	Storage (GB)
General-purpose	t2.nano	\$0.006	0.05	1	Variable	0.5	EBS only
	t2.micro	\$0.012	0.11	1	Variable	1.0	EBS only
	t2.small	\$0.023	0.21	1	Variable	2.0	EBS only
	t2.medium	\$0.047	0.4	2	Variable	4.0	EBS only
	t2.large	\$0.094	0.9	2	Variable	8.0	EBS only
	t2.xlarge	\$0.188	1.7	4	Variable	16.0	EBS only
	t2.2xlarge	\$0.376	3.5	8	Variable	32.0	EBS only
	m4.large	\$0.108	1.0	2	6.5	8.0	EBS only
	m4.xlarge	\$0.215	2.0	4	13	16.0	EBS only
	m4.2xlarge	\$0.431	4.0	8	26	32.0	EBS only
	m4.4xlarge	\$0.862	8.0	16	54	64.0	EBS only
	m4.10xlarge	\$2.155	20.0	40	125	160.0	EBS only
	m4.16xlarge	\$3.447	31.9	64	188	256.0	EBS only

	c3.4xlarge	\$0.840	7.8	16	55	30.0	2 × 160 SSD
	c3.8xlarge	\$1.680	15.6	32	108	60.0	2 × 320 SSD

Figure 6.15 Price and characteristics of on-demand general-purpose and compute-optimized EC2 instances in the Virginia region of the United States in February 2017. When AWS started, one EC2 computer unit was equivalent to a 1.0–1.2 GHz AMD Opteron or Intel Xeon of 2006. Variable instances are the newest and cheapest category. They offer the full performance of a high-frequency Intel CPU core if your workload utilizes less than 5% of the core on average over 24 h, such as for serving web pages. AWS also offers Spot Instances at a much lower cost (about 25%). With Spot Instances, customers set the price they are willing to pay and the number of instances they are willing to run, and then AWS runs the bids when the spot price drops below their level. AWS also offers Reserved Instances for cases where customers know they will use most of the instance for a year. They pay a yearly fee per instance and then an hourly rate that is about 30% of column 1 to use the service. If a Reserved Instance is used 100% for a whole year, the average cost per hour including amortization of the annual fee will be about 65% of the rate in the first column. EBS is Elastic Block Storage, which is a raw block-level storage system found elsewhere on the network, rather than in a local disk or local solid state disk (SSD) within the same server as the VM.

	Instance	Per hour	Ratio to m4.large	Virtual cores	Compute units	Memory (GiB)	Storage (GB)
GPU	p2.xlarge	\$0.900	8.3	4	12	61.0	EBS only
	p2.8xlarge	\$7.200	66.7	32	94	488.0	EBS only
	p2.16xlarge	\$14.400	133.3	64	188	732.0	EBS only
	g2.2xlarge	\$0.650	6.0	8	26	15.0	60 SSD
	g2.8xlarge	\$2.600	24.1	32	104	60.0	2 × 120 SSD
FPGA	f1.2xlarge	\$1.650	15.3	8 (1 FPGA)	26	122.0	1 × 470 SSD
	f1.16xlarge	\$13.200	122.2	64 (8 FPGA)	188	976.0	4 × 940 SSD
Memory-optimized	x1.16xlarge	\$6.669	61.8	64	175	976.0	1 × 1920 SSD
	x1.32xlarge	\$13.338	123.5	128	349	1,952.0	2 × 1920 SSD
	r3.large	\$0.166	1.5	2	6.5	15.0	1 × 32 SSD
	r3.xlarge	\$0.333	3.1	4	13	30.5	1 × 80 SSD
	r3.2xlarge	\$0.665	6.2	8	26	61.0	1 × 160 SSD
	r3.4xlarge	\$1.330	12.3	16	52	122.0	1 × 320 SSD

	r4.large	\$0.133	1.2	2	7	15.3	EBS only
	r4.xlarge	\$0.266	2.5	4	14	30.5	EBS only
	r4.2xlarge	\$0.532	4.9	8	27	61.0	EBS only
	r4.4xlarge	\$1.064	9.9	16	53	122.0	EBS only
	r4.8xlarge	\$2.128	19.7	32	99	244.0	EBS only
	r4.16xlarge	\$4.256	39.4	64	195	488.0	EBS only
Storage-optimized	i2.xlarge	\$0.853	7.9	4	14	30.5	1 × 800 SSD
	i2.2xlarge	\$1.705	15.8	8	27	61.0	2 × 800 SSD
	i2.4xlarge	\$3.410	31.6	16	53	122.0	4 × 800 SSD
	i2.8xlarge	\$6.820	63.1	32	104	244.0	8 × 800 SSD
	d2.xlarge	\$0.690	6.4	4	14	30.5	3 × 2000 HDD
	d2.2xlarge	\$1.380	12.8	8	28	61.0	6 × 2000 HDD
	d2.4xlarge	\$2.760	25.6	16	56	122.0	12 × 2000 HDD
	d2.8xlarge	\$5.520	51.1	36	116	244.0	24 × 2000 HDD

Figure 6.16 Price and characteristics of on-demand GPUs, FPGAs, memory-optimized, and storage-optimized EC2 instances in the Virginia region of the United States in February 2017.

the largest offers 2000 times more memory than the smallest. Rent for the cheapest instance for a whole year is just \$50.

In addition to computation, EC2 charges for long-term storage and for Internet traffic. (There is no cost for network traffic inside AWS regions.) Elastic Block Storage (EBS) costs \$0.10 per GB per month when using SSDs and \$0.045 per GB monthly for hard disk drives. Internet traffic costs \$0.01 per GB going to EC2 and \$0.09 per GB coming from EC2.

Example Calculate the cost of running the average MapReduce job in Figure 6.2 on page 438 on EC2 for several months over the years. Assume there are plenty of jobs, so there is no significant extra cost to round up so as to get an integer number of hours. Next calculate the cost per month to run all the MapReduce jobs.

Answer The first question is, what is the right size instance to match the typical server at Google? Let's assume the closest match in Figure 6.15 is a c4.large with 2 virtual cores and 3.6 GiB of memory, which costs \$0.100 per hour. Figure 6.17 calculates the average and total cost per year of running the Google MapReduce workload on EC2. The average September 2016 MapReduce job would cost a little over \$1 on EC2, and the total workload for that month would cost \$114 million on AWS.

	Aug-04	Sep-09	Sep-12	Sep-16
Average completion time (h)	0.15	0.14	0.13	0.11
Average number of servers per job	157	156	142	130
Cost per hour of EC2 c4.large instance	\$0.100	\$0.100	\$0.100	\$0.100
Average EC2 cost per MapReduce job	\$2.76	\$2.23	\$1.89	\$1.20
Monthly number of MapReduce jobs	29,000	4,114,919	15,662,118	95,775,891
Total cost of MapReduce jobs on EC2/EBS	\$80,183	\$9,183,128	\$29,653,610	\$114,478,794

Figure 6.17 Estimated cost to run the Google MapReduce workload for select months between 2004 and 2016 (Figure 6.2) using 2017 prices for AWS EC2. Because we are using 2017 prices, these are underestimates of actual AWS costs.

Example Given the cost of MapReduce jobs, imagine that your boss wants you to investigate ways to lower costs. How much might you save using AWS Spot Instances?

Answer The MapReduce jobs could be disrupted by being kicked off a spot instance, but MapReduce is designed to tolerate and restart failed jobs. The AWS Spot price for c4.large was \$0.0242 versus \$0.100, which meant a savings of \$87 million for September 2016, but there were no guarantees on the response times!

In addition to the low-cost and a pay-for-use model of utility computing, another strong attractor for cloud computing users is that the cloud-computing providers take on the risks of over-provisioning or under-provisioning. Because either mistake could be fatal, risk avoidance is a godsend for startup companies. If too much of the precious investment is spent on servers before the product is ready for heavy use, a company could run out of money. If the service suddenly became popular but there weren't enough servers to match the demand, a company could

make a very bad impression with the potential new customers it desperately needs in order to grow.

The poster child for this scenario is FarmVille from Zynga, a social networking game on Facebook. Before FarmVille was announced, the largest social game was about five million daily players. FarmVille had one million players 4 days after launching and 10 million players after 60 days. After 270 days, it had 28 million daily players and 75 million monthly players. Because FarmVille is deployed on AWS, it is able to grow seamlessly with the number of users. Moreover, it is able to shed load based on customer demand and time of day.

FarmVille was so successful that Zynga decided to open its own data centers in 2012. In 2015, Zynga returned to AWS, deciding it was better to let AWS run its data centers ([Hamilton, 2015](#)). When FarmVille dropped from the most popular Facebook application to 110th in 2016, Zynga was able to downsize gracefully with AWS, much as it grew with AWS in the beginning.

In 2014, AWS offered a new service that hearkened back to the timesharing days of the 1960s that John McCarthy was referring to in the opening quote of this section. Instead of managing virtual machines in the cloud, *Lambda* lets users supply a function in source code (such as Python) and lets AWS automatically manage the resources required by that code to scale with input size and to make it highly available. Google Cloud Compute Functions and Microsoft Azure Functions are equivalent capabilities from competing cloud providers. As [Section 6.10](#) explains, Google App Engine originally offered a quite similar service in 2008.

This trend is referred to as *Serverless Computing*, in that users don't have to manage servers (but these functions *are* in fact run on servers). The tasks provided include operating system maintenance, capacity provisioning and automatic scaling, code and security patch deployment, and code monitoring and logging. It runs code in response to events, such as an http request or database update. One way to think of Serverless Computing is as a set of processes running in parallel across the entire WSC that share data through a disaggregated storage service such as AWS S3.

There is no cost for Serverless Computing when a program is idle. The AWS accounting is six orders of magnitude finer than EC2, recording usage per 100 ms instead of per hour. Cost varies depending on the amount of memory needed, but if your program used 1 GiB of memory, the cost is \$0.000001667 per 100 ms or about \$6 per hour.

Serverless Computing can be thought of as the next evolutionary step toward realizing the cloud computing ideals of the data center as a computer, as pay-as-you-go pricing, and as a means for automatic dynamic scaling.

Cloud computing has made the benefits of WSC available to everyone. Cloud computing offers cost associativity with the illusion of infinite scalability at no extra cost to the user: 1000 servers for 1 h cost no more than 1 server for 1000 h. It is up to the cloud computing provider to ensure that there are enough servers, storage, and Internet bandwidth available to meet the demand. The previously mentioned optimized supply chain, which drops time-to-delivery to a week for new computers, is a considerable aid in providing that illusion without

bankrupting the provider. This transfer of risks, cost associativity, pay-as-you-go pricing, and greater security is a powerful argument for companies of varying sizes to use cloud computing.

How Big Is the AWS Cloud?

AWS started in 2006 and grew so large that Amazon.com, rather than use a separate computing infrastructure, became one of AWS's customers in 2010. [Figure 6.18](#) shows that AWS had facilities in 16 locations around the world in 2017, with two more on the way. As a point of interest, [Figures 6.19](#) and [6.20](#) show similar maps for Google and Microsoft.

Each AWS location consists of two to three nearby facilities (one or two kilometers apart) called *availability zones*. They are so named because it should be safe to have your software running on two of them to ensure dependability as it is unlikely that both would fail simultaneously because of power outages or a natural disaster ([Hamilton, 2014](#)). These 16 locations contain 42 availability zones, and each of those zones has one or more WSCs. In 2014 each WSC had at least 50,000 servers, and some had more than 80,000.

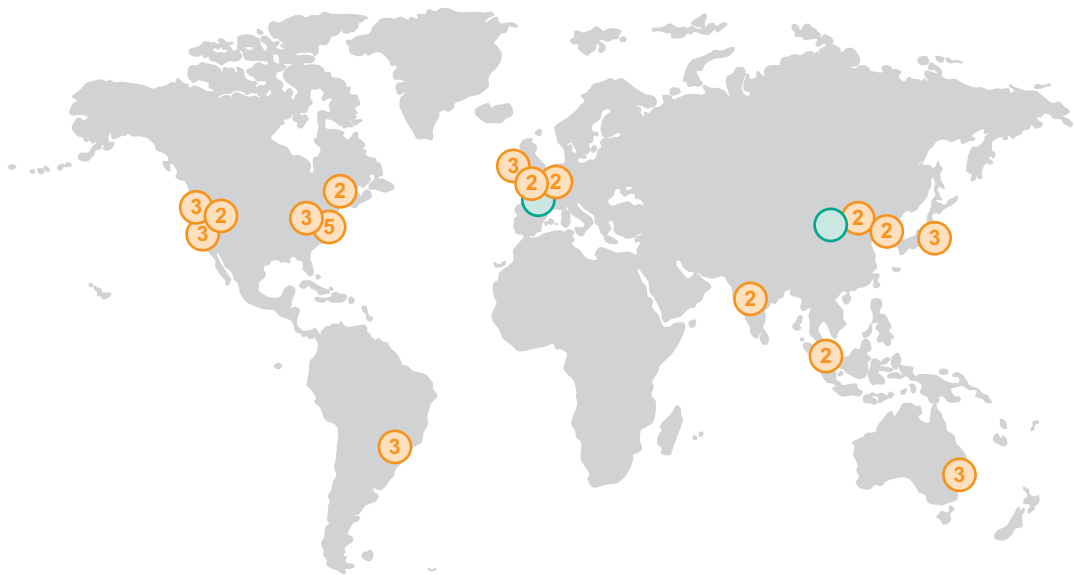

Figure 6.18 In 2017 AWS had 16 sites (“regions”), with two more opening soon. Most sites have two to three *availability zones*, which are located nearby but are unlikely to be affected by the same natural disaster or power outage, if one were to occur. (The number of availability zones are listed inside each circle on the map.) These 16 sites or regions collectively have 42 availability zones. Each availability zone has one or more WSCs. <https://aws.amazon.com/about-aws/global-infrastructure/>.

Figure 6.19 In 2017 Google had 15 sites. In the Americas: Berkeley County, South Carolina; Council Bluffs, Iowa; Douglas County, Georgia; Jackson County, Alabama; Lenoir, North Carolina; Mayes County, Oklahoma; Montgomery County, Tennessee; Quilicura, Chile; and The Dalles, Oregon. In Asia: Changhua County, Taiwan; Singapore. In Europe: Dublin, Ireland; Eemshaven, Netherlands; Hamina, Finland. <https://www.google.com/about/datacenters/inside/locations/>.

Hamilton (2017) says its best to have at least three WSCs per region. The reason is simply that when one WSC fails, the other in the region needs to take on the load of the failed WSC. If there were only one other WSC, each would have to reserve half of its capacity for failover. With three, they could be used at two-thirds of capacity and still handle a quick failover. The more data centers you have, the less reserved excess capacity; AWS has regions with more than 10 WSCs.

We have found two published estimates of the total number of servers in AWS in 2014. One estimate was 2 million servers, when AWS had just 11 regions and 28 availability zones (Clark, 2014). Another estimate was between 2.8 and 5.6 million servers (Morgan 2014). If we extrapolate from 2014 to 2017 based on the increased number of availability zones, the estimates will grow to 3.0 million servers on the low end and 8.4 million on the high end. The total number of WSCs (data centers) is 84–126. Figure 6.21 shows the growth over time, using extrapolations from these two projections to offer high and low estimates of the number of servers and WSCs over time.

AWS is understandably mum on the actual number. They said that AWS had more than 1 million customers in 2014 and that “every day AWS adds enough physical server capacity equivalent to that needed to support Amazon.com in 2004” when it was a \$7 billion annual revenue company (Hamilton, 2014).

One way to check the validity of these estimates is to look at investments. Amazon spent \$24 billion in capital investments in property and equipment

Figure 6.20 In 2017 Microsoft had 34 sites, with four more opening soon. <https://azure.microsoft.com/en-us/regions/>.

Figure 6.21 Growth of AWS regions and availability zones (right vertical axis) over time. Most regions have two or three availability zones. Each availability zone can have one or more WSCs, with the largest having more than 10 WSCs. Each WSC has at least 50,000 servers, with the biggest having more than 80,000 servers (Hamilton, 2014). Based on two published estimates for the number of AWS servers in 2014 (Clark, 2014; Morgan 2014), we project the number of servers per year (left vertical axis) and WSCs (right vertical axis) as a function of the actual number of availability zones.

between 2013 and 2015, and one estimate is that two-thirds of that investment was for AWS (Gonzalez and Day 2016; Morgan 2016). Assume that it takes a year to construct a new WSC. The estimate in Figure 6.21 for 2014 to 2016 is from 34 to 51 WSCs. The cost per AWS WSC will then be \$310 million to \$470 million. Hamilton states that “even a medium sized datacenter (WSC) will likely exceed \$200M.” (Hamilton, 2017). He goes on to say that today cloud providers currently have “ $O(10^2)$ ” WSCs; Figure 6.21 estimate is 84–126 AWS WSCs. Despite the fuzziness of these estimates, they appear to be surprisingly consistent. He goes on to predict that to meet the future demands, the largest cloud providers will eventually rise to “ $O(10^5)$ ” WSCs, or 1000 times more WSCs than today!

No matter how many servers and WSCs are in the cloud, two cross-cutting issues that shape the cost-performance of WSCs and thus cloud computing are the WSC network and the efficiency of the server hardware and software.

6.6

Cross-Cutting Issues

Net gear is the SUV of the datacenter.

James Hamilton (2009)

Preventing the WSC Network From Being a Bottleneck

Figure 6.22 shows the network demands doubling every 12–15 months for Google, resulting in a $50\times$ growth in traffic from the servers in Google’s fleet of WSCs in just 7 years. Clearly, without great care, the WSC network could easily become a performance or cost bottleneck.

In the previous edition, we pointed out that a data center switch could cost almost \$1 million, or more than 50 times as much as a Top of Rack switch. Not only was such a switch expensive, the resulting oversubscription affected the design of software and the placement of services and data within the WSC. The WSC network bottlenecks constrained data placement, which in turn complicated WSC software. Because this software is one of the most valuable assets of a WSC company, the cost of this added complexity was significant.

The ideal WSC network would be a black box whose topology and bandwidth are uninteresting because there are no restrictions: any workload could

Figure 6.22 Network traffic from all the servers in Google’s WSCs over 7 years (Singh et al., 2015).

be placed anywhere and optimized for server utilization rather than network traffic locality. [Vahdat et al. \(2010\)](#) proposed borrowing networking technology from supercomputing to overcome the price and performance problems. The latter proposed a networking infrastructure that could scale to 100,000 ports and 1 Pbit/s of bisection bandwidth. A major benefit of these novel data center switches is to simplify the software challenges because of oversubscription.

Since that time, many companies with WSC have designed their own switches to overcome these challenges ([Hamilton, 2014](#)). [Singh et al. \(2015\)](#) reported on several generations of custom networks used inside Google WSCs, which [Figure 6.23](#) lists.

To keep costs down, they built their switches from standard commodity switch chips. They found that the features of traditional data center switches that were used in part to justify their high costs—such as decentralized network routing and protocols to manage support of arbitrary deployment scenarios—were unnecessary in a WSC because the network topology could be planned in advance of deployment

Data center generation switch	First deployed	Merchant silicon	Top of rack (ToR) switch config	Edge aggregation block	Spine block	Fabric speed	Host speed	Bisection BW
Four-Post CRs	2004	Vendor	48×1 Gbps	—	—	10 Gbps	1 Gbps	2 Tbps
Firehose 1.0	2005	8×10 Gbps 4×10 Gbps (ToR)	2×10 Gbps up 24×1 Gbps down	$2 \times 32 \times 10$ Gbps	32×10 Gbps	10 Gbps	1 Gbps	10 Tbps
Firehose 1.1	2006	8×10 Gbps	4×10 Gbps up 48×1 Gbps down	64×10 Gbps	32×10 Gbps	10 Gbps	1 Gbps	10 Tbps
Watchtower	2008	16×10 Gbps	4×10 Gbps up 48×1 Gbps down	$4 \times 128 \times 10$ Gbps	128×10 Gbps	10 Gbps	$n \times 1$ Gbps	82 Tbps
Saturn	2009	24×10 Gbps	24×10 Gbps	$4 \times 288 \times 10$ Gbps	288×10 Gbps	10 Gbps	$n \times 10$ Gbps	207 Tbps
Jupiter	2012	16×40 Gbps	16×40 Gbps	$8 \times 128 \times 40$ Gbps	128×40 Gbps	10/40 Gbps	$n \times 10$ Gbps/ $n \times 40$ Gbps	1300 Tbps

Figure 6.23 Six generations of network switches deployed at Google WSCs ([Singh et al., 2015](#)). The Four-Post CRs used commercial 512 port, 1 Gbit/s Ethernet switches, and 48-port, 1 Gbit/s Ethernet Top of Rack (ToR) switches, which allowed 20,000 servers in the array. The goal of Firehose 1.0 was to deliver 1 Gbps of nonblocking bisection bandwidth to each of 10,000 servers, but it ran into problems with the low connectivity of the ToR switch that caused problems when links failed. Firehose 1.1 was the first custom-designed switch with better connectivity in the ToR switch. Watchtower and Saturn followed in the same footsteps, but used new, faster merchant switch chips. Jupiter uses 40 Gbps links and switches to deliver more than 1 Pbit/s of bisection bandwidth. [Section 6.7](#) describes the Jupiter switch and the Edge Aggregation and Spine Blocks of Clos networks in more detail.

and the network had only a single operator. Google instead used centralized control that relied on a common configuration that was copied to all data center switches. The modular hardware design and robust software control allowed these switches to be used both for inside the WSC and for wide area networks between WSCs. Google scaled the bandwidth of its WSCs networks by 100X in a decade, and offered more than 1 Pbit/s of bisection bandwidth in 2015.

Using Energy Efficiently Inside the Server

Although PUE measures the efficiency of a WSC, it has nothing to say about what goes on inside the IT equipment. Thus, another source of electrical inefficiency is the power supply *inside* the server, which converts input of high voltage to the voltages that chips and disks use. In 2007 many power supplies were 60%–80% efficient, which meant there were greater losses inside the server than there were going through the many steps and voltage changes from the high-voltage lines at the utility tower to supply the low-voltage lines at the server. One reason was that the power supply was often oversized in watts for what was on the motherboard. Moreover, such power supplies were typically at their worst efficiency at 25% load or less, even though, as [Figure 6.3](#) on page 441 shows, many WSC servers operate in that range. Computer motherboards also have voltage regulator modules (VRMs), and they can have relatively low efficiency as well.

[Barroso and Hölzle \(2007\)](#) said the goal for the whole server should be *energy proportionality*; that is, servers should consume energy in proportion to the amount of work performed. A decade later, we’ve gotten close but have not hit that ideal goal. For example, the best-rated SPECpower servers in [Chapter 1](#) still use about 20% of the full power when idle and almost 50% of full power at just 20% load. That represents huge progress since 2007 when an idle computer used 60% of full power and 70% at a 20% load, but there is still room to improve.

Systems software is designed to use all of an available resource if it potentially improves performance, without concern for the energy implications. For example, operating systems use all of memory for program data or for file caches, although much of the data will likely never be used. Software architects need to consider energy as well as performance in future designs ([Carter and Rajamani, 2010](#)).

Given the background from these six sections, we are now ready to appreciate the work of the Google WSC architects.

Because many companies with WSCs are competing vigorously in the marketplace, most have been reluctant to share their latest innovations with the public (and each other). Fortunately, Google has continued its tradition of providing details on recent WSCs for new editions of this book, once again making this

edition likely the most up-to-date public description of a Google WSC, which is representative of the current state-of-the-art.

Power Distribution in a Google WSC

We start with power distribution. Although there are many variations deployed, in North America electric power typically goes through multiple voltage changes on the way to the server, starting with the high-voltage lines at the utility tower of over 110,000 V.

For large-scale sites with multiple WSCs, power is delivered to on-site substations (Figure 6.24). The substations are sized for hundreds of megawatts of power. The voltage is reduced to between 10,000 and 35,000 V for distribution to WSCs on the site.

Near the buildings of the WSC, the voltage is further reduced to around 400 V (Figure 6.25) for distribution to the rows of servers on the data center floor. (480 V is common in North America, but 400 V in the rest of the world; Google uses 415 V.) To prevent the whole WSC from going offline if power is lost, WSCs have their version of an uninterruptible power supply (UPS), just as most servers do in conventional data centers. Diesel generators are connected to the power distribution system at this level to provide power in the event of an issue with the utility power. Although most outages are less than a few minutes, WSCs store thousands of gallons of diesel on site for an extended event. The operators even make provisions with local fuel companies for continuous delivery of diesel should a site need to operate from generators for days or weeks.

Inside the WSC, power is delivered to the racks via copper bus ducts that run above each row of racks, as Figure 6.26 shows. The last step splits the three-phase power into three separate single-phase powers of 240–277 V delivered by power

Figure 6.24 An on-site substation.

Figure 6.25 This image shows transformers, switch gear, and generators in close proximity to a WSC.

Figure 6.26 Row of servers with the copper bus ducts above that distribute 400 V to the servers. Although hard to see, they are above the shelf on the right side of the photo. It also shows a cold aisle that operators use to service the equipment.

cables to the rack. Near the top of the rack, power converters turn the 240 V AC current into 48 V DC to bring the voltage down to what boards can use.

In summary, power is distributed in a hierarchy in a WSC, with each level of the hierarchy corresponding to a distinct failure and maintenance unit: the whole WSC, arrays, rows, and racks. Software is aware of the hierarchy, and it spreads work and storage topographically to increase dependability.

WSCs around the world have different distribution voltages and frequencies, but the overall design is similar. The primary places for improvement in power

efficiency are in the voltage transformers at each step, but these are highly optimized components, so there is little opportunity left.

Cooling in a Google WSC

Now that we can deliver power from the utility poles to the floor of the WSC, we need to remove the heat generated from using it. There are considerably more opportunities for improvement in the cooling infrastructure.

One of the easiest ways to improve energy efficiency is simply to run the IT equipment at higher temperatures so that the air does not need to be cooled as much. Google runs its equipment at 80+°F (27+°C), which is considerably higher than traditional data centers that are so cold that you need to wear a jacket.

Airflow is carefully planned for the IT equipment, even using Computational Fluid Dynamics simulation to design the facility. Efficient designs preserve the temperature of the cool air by reducing the chances of it mixing with hot air.

For example, most WSCs today have alternating aisles of hot air and cold air by orienting servers in opposite directions in alternating rows of racks so that hot exhaust blows in alternating directions. They are referred to as *hot aisles* and *cold aisles*. Figure 6.26 shows a cold aisle that people use to service the servers, and Figure 6.27 shows the hot aisle. The hot air from the hot aisle rises through ducts into the ceiling.

Figure 6.27 Hot aisle in a Google data center, which is clearly not designed to accommodate people.

Figure 6.28 The cool air blows into the room containing the aisles of servers. The hot air goes through large vents into the ceilings where it is cooled before returning to these fans.

In conventional data centers, each server relies on internal fans to ensure a sufficient flow of cool air over the hot chips to maintain their temperature. These mechanical fans are one of the weakest components in servers; for example, the MTBF of fans is 150,000 h versus 1,200,000 h for disks. In a Google WSC, the server fans work synergistically with dozens of giant fans in the room to ensure airflow for the whole room (Figure 6.28). This division of labor means the small server fans use as little power as possible while delivering maximum performance at the worst-case power and ambient conditions. The large fans are controlled using air pressure as the control variable. The fan speeds are adjusted to maintain a minimum pressure difference between the hot and cold aisles.

To cool this hot air, they add large-scale fan-coils at either end of the rows of racks. Hot air from the racks is delivered to the fan-coils above via a horizontal plenum inside the hot aisle. (Two rows share the pair of cooling coils, as they are placed above the cold aisle between the two rows.) The cooled air is sent via a plenum in the ceiling to the wall with the big fans in Figure 6.28, which return the cooled air to the room containing the racks.

We'll describe how to remove the heat from the water in the cooling coils shortly, but let's reflect on the architecture so far. It separates the racks from the cooling capacity provided by the fan-coils, which allows for sharing of cooling across two rows of racks in the WSC. Thus, it efficiently provides more cooling to high-power racks and less to low-power racks. With thousands of racks in a WSC, they are unlikely to be identical, so power variability between racks is common, which this design accommodates.

Cool water is supplied to the individual fan-coils via a network of pipes from a cooling plant. Heat is transferred into the water via forced convection in the cooling coils, and warm water returns to a cooling plant.

To improve the efficiency of WSCs, architects try to use the local environment to remove the heat whenever possible. Evaporative *cooling towers* are common in WSCs to leverage the colder outside air to cool the water instead of it being chilled mechanically. The temperature that matters is called the *wet-bulb temperature*, which is the lowest temperature that can be achieved by evaporating water with air. It is the temperature a parcel of air would have if it were cooled to saturation (100% relative humidity) by the evaporation of water into it, with the latent heat being supplied by the parcel. Wet-bulb temperature is measured by blowing air at the bulb end of a thermometer that has water on it.

Warm water is sprayed inside in the cooling tower and collected in pools at the bottom, transferring heat to the outside air via evaporation and thereby cooling the water. This technique is called *water-side economization*. Figure 6.29 shows the steam rising above cooling towers. An alternative is to use cold water instead of crisp air. Google's WSC in Finland uses a water-to-water heat exchanger that takes the frigid water from the Gulf of Finland to chill the warm water from inside the WSC.

The cooling tower system uses water caused by evaporation in the cooling towers. For example, an 8-MW facility might need 70,000–200,000 gallons of water per day, thus the desire for the WSC to be located near ample sources of water.

Although the cooling plant is designed so that heat can be removed without artificial cooling most of the time, mechanical chillers aid in rejecting the heat in some regions when the weather is warm.

Figure 6.29 Steam rising from the cooling towers that transfer heat to the air from the water used to cool equipment.

Racks of a Google WSC

We saw how Google gets power to rack and how it cools the hot air that exhausts from the rack. Now we're ready to explore the rack itself. [Figure 6.30](#) shows a typical rack found inside a Google WSC. To put this rack into context, a WSC consists of multiple arrays (which Google calls clusters). Although arrays vary in size, some have one to two dozen rows with each row holding two to three dozen racks.

The 20 slots shown the middle of the rack in [Figure 6.30](#) hold the servers. Depending on their width, up to four servers can be placed in a single tray. The power converters near the top of the rack turn the 240 V AC current into 48 V DC, which is run on copper bus bars down the back of the rack to power the servers.

The diesel generators that provide backup power for the whole WSC take tens of seconds before they can offer power. Instead of populating a large room with

Figure 6.30 A Google rack for its WSC. Its dimensions are about 7 ft high, 4 ft wide, and 2 ft deep ($2\text{ m} \times 1.2\text{ m} \times 0.5\text{ m}$). The Top of Rack switches are indeed at the top of this rack. Next comes the power converter that converts from 240 V AC to 48 V DC for the servers in the rack using a bus bar at the back of the rack. Next is the 20 slots (depending on the height of the server) that can be configured for the various types of servers that can be placed in the rack. Up to four servers can be placed per tray. At the bottom of the rack are high-efficiency distributed modular DC uninterruptible power supply (UPS) batteries.

enough batteries to power the whole WSC for several minutes—which was a common practice in the early WSCs—Google puts small batteries at the bottom of each rack. Because UPS is distributed to each rack, the cost is incurred only as racks are deployed, instead of paying upfront for the UPS capacity of a full WSC. These batteries are also better than the traditional batteries because they are on the DC side after the voltage conversions, and they use an efficient charging scheme. In addition, replacing the 94%-efficient lead batteries with the 99.99%-efficient local UPS helps to lower the PUE. It's a very efficient UPS system.

It is comforting that the top of the rack in [Figure 6.30](#) does indeed contain the Top of Rack switch, which we describe next.

Networking in a Google WSC

The Google WSC network uses a topology called *Clos*, which is named after the telecommunications expert who invented it ([Clos, 1953](#)). [Figure 6.31](#) shows the structure of the Google Clos network. It is a multistage network that uses low port-count (“low radix”) switches, offers fault tolerance, and increases both the network scale and its bisection bandwidth. Google increases the scale simply by adding stages to the multistage network. The fault tolerance is provided by its inherent redundancy, which means a failure of any link has only a small impact on the overall network capacity.

As [Section 6.6](#) describes, Google builds customer switches from standard commodity switch chips and uses centralized control for network routing and management. Every switch is given a consistent copy of the current topology of the network, which simplifies the more complex routing of a Clos network.

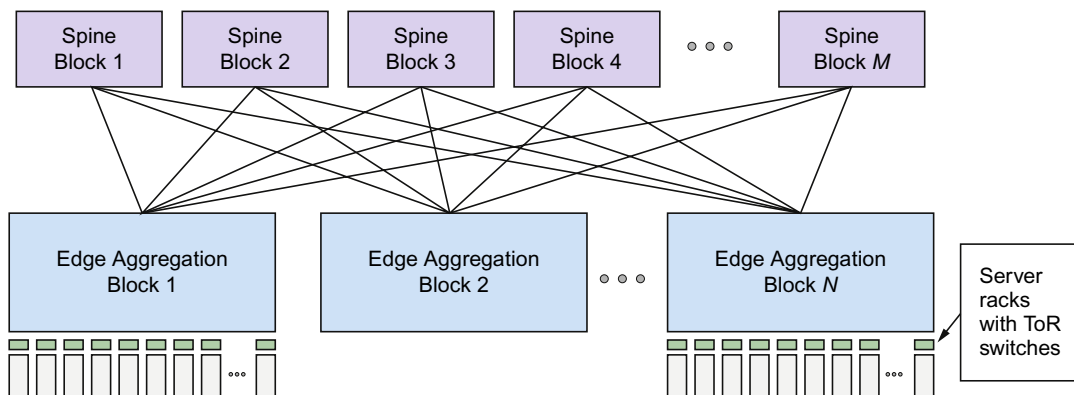

Figure 6.31 A Clos network has three logical stages containing crossbar switches: ingress, middle, and egress. Each input to the ingress stage can go through any of the middle stages to be routed to any output of the egress stage. In this figure, the middle stages are the M Spine Blocks, and the ingress and egress stages are in the N Edge Activation Blocks. [Figure 6.22](#) shows the changes in the Spine Blocks and the Edge Aggregation Blocks over many generations of Clos networks in Google WSCs.

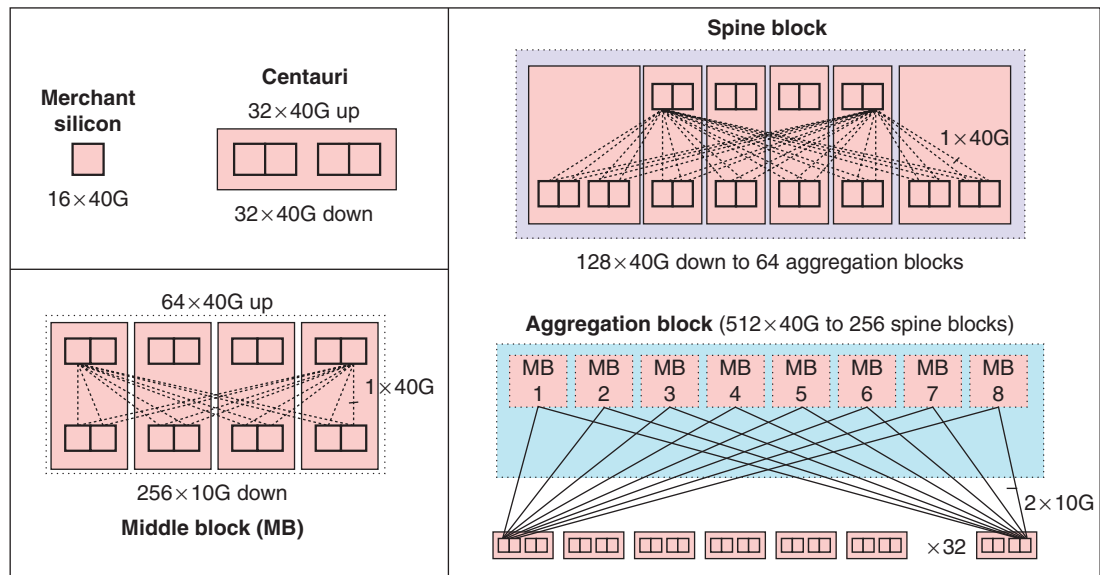

Figure 6.32 Building blocks of the Jupiter Clos network.

The latest Google switch is Jupiter, which is the switch's sixth generation. [Figure 6.32](#) shows the building blocks of the switch, and [Figure 6.33](#) shows the wiring of the middle blocks housed in racks. All the cables use bundles of optical fibers.

The commodity switch chip for Jupiter is a 16×16 crossbar using 40 Gbps links. The Top of Rack switch has four of these chips, which are configured with 48 40-Gbps links to the servers and 16 40-Gbps links to the network fabric, yielding an oversubscription of just 3:1, which is better than earlier generations. Moreover, this generation was the first time that servers were offered with 40-Gbps links.

The middle blocks in [Figures 6.32](#) and [6.33](#) consist of 16 of the switch chips. They use two stages, with 256 10-Gbps links for the Top of Rack connectivity and 64 40-Gbps links to connect to the rest of the network fabric through the spine. Each of the chips in the Top of Rack switch connects to eight middle blocks using dual redundant 10-Gbps links.

Each aggregation block is connected to the spine block with 512 40-Gbps links. A spine block uses 24 switch chips to offer 128 40-Gbps ports to the aggregation blocks. At the largest scale, they use 64 aggregation blocks to provide dual redundant links. At this maximum size, the bisection bandwidth is an impressive $1.3 \text{ Pbit} (10^{15})$ per second.

Note that the whole Internet might have a bisection bandwidth of just 0.2 Pbit/s; one reason is that Jupiter was built for a high bisection bandwidth, but the Internet was not.

Figure 6.33 Middle blocks of the Jupiter switches housed in racks. Four are packed in a rack. A rack can hold two spine blocks.

Servers in a Google WSC

Now that we have seen how to power, cool, and communicate, we are finally ready to see the computers that do the actual work of the WSC.

The example server in [Figure 6.34](#) has two sockets, each containing an 18-core Intel Haswell processor running at 2.3 GHz (see Section 5.8). The photo shows 16 DIMMs, and these servers are typically deployed with 256 GB total of DDR3-1600 DRAM. The Haswell memory hierarchy has two 32 KiB L1 caches, a 256 KiB L2 cache, and 2.5 MiB of L3 cache per core, resulting in a 45 MiB L3 cache. The local memory bandwidth is 44 GB/s with a latency of 70 ns, and the intersocket bandwidth is 31 GB/s with a latency of 140 ns to remote memory. [Kanev et al. \(2015\)](#) highlighted the differences between the SPEC benchmark suite and a WSC workload. An L3 cache is barely needed for SPEC, but it is useful for a real WSC workload.

The baseline design has a single network interface card (NIC) for a 10 Gbit/s Ethernet link, although 40 Gbit/s NICs are available. (Other cloud providers

Figure 6.34 An example server from a Google WSC. The Haswell CPUs (2 sockets \times 18 cores \times 2 threads = 72 “virtual cores” per machine) have 2.5 MiB last level cache per core or 45 MiB using DDR3-1600. They use the Wellsburg Platform Controller Hub and have a TFP of 150 W.

moved to 25 Gbit/s or multiples thereof.) While the photo in [Figure 6.34](#) shows two SATA disk drives, each of which can contain up to 8 TB, the server also can be configured with SSD flash drives with 1 TB of storage. The peak power of the baseline is about 150 watts. Four of these servers can fit in a slot of the rack in [Figure 6.30](#).

This baseline node is supplemented to offer a storage (or “diskfull”) node. The second unit contains 12 SATA disks and is connected to the server over PCIe. Peak power for a storage node is about 300 watts.

Conclusion

In the previous edition, the Google WSC we described had a PUE of 1.23 in 2011. As of 2017, the average PUE of the whole Google fleet of 16 sites dropped to 1.12, with the Belgium WSC leading the way with a 1.09 PUE. The energy-saving techniques include

- Operating servers at higher temperatures means that air has to be chilled only to 80+°F (27°C) instead of the traditional 64–71°F (18–22°C).
- A higher target for cold air temperature helps put the facility more often within the range that can be sustained by cooling towers, which are more energy-efficient than traditional chillers.

- Deploying WSCs in temperate climates to allow use of evaporative cooling exclusively for large portions of the year.
- Adding large fans for entire rooms to work in concert with the small fans of the servers to reduce energy while satisfying worst-case scenarios.
- Averaging the cooling per server to whole racks of servers by deploying the cooling coils per row to accommodate warmer and cooler racks.
- Deploying extensive monitoring hardware and software to measure actual PUE versus designed PUE improves operational efficiency.
- Operating more servers than the worst-case scenario for the power distribution system would suggest. It is safe since it's statistically improbable that thousands of servers would all be highly busy simultaneously as long as there is a monitoring system to off-load work in the unlikely case that they did (Fan et al., 2007; Ranganathan et al., 2006). PUE improves because the facility is operating closer to its fully designed capacity, where it is at its most efficient because the servers and cooling systems are not energy-proportional. Such increased utilization reduces demand for new servers and new WSCs.

It will be interesting to see what innovations remain to further improve the WSC efficiency so that we are good guardians of our environment. It is hard to imagine now how engineers might halve the power and cooling overhead of a WSC prior to the next edition of this book, as they did between the previous edition and this one.

6.8

Fallacies and Pitfalls

Despite WSC being just 15 years old, WSC architects like those at Google have already uncovered many pitfalls and fallacies about WSCs, often the hard way. As we said in the introduction, WSC architects are today's Seymour Crays.

Fallacy *Cloud computing providers are losing money.*

When AWS was announced, a popular question about cloud computing was whether it was profitable at the low prices at the time. Amazon Web Services has grown so large that it must be recorded separately in Amazon's quarterly reports. To the surprise of some, AWS has proved to be the most profitable portion of the company. AWS had \$12.2 billion in revenue for 2016, with an operating margin of 25%, whereas Amazon's retail operations had an operating margin of less than 3%. AWS is consistently responsible for three-fourths of Amazon's profits.

Pitfall *Focusing on average performance instead of 99th percentile performance.*

As Dean and Barroso (2013) observed, developers of WSC services worry about the tail more than they care about the mean. If some customers get terrible performance, that experience can drive them away to a competitor, and they'll never return.

Pitfall *Using too wimpy a processor when trying to improve WSC cost-performance.*

Amdahl's Law still applies to WSC. There will be some serial work for each request and that can increase request latency if this work runs on a slow server (Hölzle, 2010; Lim et al., 2008). If the serial work increases latency, then the cost of using a wimpy processor must include the software development costs to optimize the code to return it to the lower latency. The larger number of threads of many slow servers can also be more difficult to schedule and load balance, and thus the variability in thread performance can lead to longer latencies. When required to wait for the longest task, a 1-in-1000 chance of bad scheduling is probably not an issue with 10 tasks, but problematic with 1000 tasks.

Many smaller servers can also lead to lower utilization because it's clearly easier to schedule fewer things. Finally, even some parallel algorithms get less efficient when the problem is partitioned too finely. The Google rule of thumb is to use the low-end range of server class computers (Barroso and Hölzle, 2009).

As a concrete example, Reddi et al. (2010) compared embedded microprocessors (Atom) and server microprocessors (Nehalem Xeon) running the Bing search engine. They found that the latency of a query was about three times longer on Atom than on Xeon. Moreover, the Xeon was more robust. As load increases on Xeon, quality of service degrades gradually and modestly. The Atom design quickly violates its quality-of-service target as it tries to absorb additional load. Although the Atom design is more energy-efficient, the response time affects revenue, and the revenue loss is likely much greater than the cost savings of less energy. Energy-efficient designs that cannot match the response-time goals are unlikely to be deployed; we'll see another version of this pitfall lesson in the next chapter (Section 7.9).

This behavior translates directly into search quality. Given the importance of latency to the user, as Figure 6.12 suggests, the Bing search engine uses multiple strategies to refine search results if the query latency has not yet exceeded a cutoff latency. The lower latency of the larger Xeon nodes means they can spend more time refining search results. Thus, even when the Atom had almost no load, it gave worse answers in 1% of the queries than Xeon. At normal loads, 2% of the answers were worse.

Kanev et al. (2015) has more recent, yet consistent, results.

Pitfall *Inconsistent measure of PUE by different companies.*

Google's PUE measurements start from the power before it reaches the substation. Some measure at the entrance to the WSC, which skips voltage step downs that represent a 6% loss. There will also be different results depending on the season of the year if the WSC relies on the atmosphere to help cool the system. Finally, some report the design goal of the WSC instead of measuring the resulting system. The most conservative and best PUE measurement is a running average of the past 12 months of the measured PUE, starting from the feed of the utility.

Fallacy *Capital costs of the WSC facility are higher than for the servers that it houses.*

Although a quick look at [Figure 6.13](#) on page 453 might lead one to that conclusion, that quick glimpse ignores the length of amortization for each part of the full WSC. However, the facility lasts 10–15 years, whereas the servers need to be repurchased every 3 or 4 years. Using the amortization times in [Figure 6.13](#) of 10 years and 3 years, respectively, the capital expenditures over a decade are \$72 million for the facility and $3.3 \times \$67$ million, or \$221 million, for servers. Thus, the capital costs for servers in a WSC over a decade are a factor of three higher than for the WSC facility.

Pitfall *Trying to save power with inactive low power modes versus active low power modes.*

[Figure 6.3](#) on page 441 shows that the average utilization of servers is between 10% and 50%. Given the concern about operational costs of a WSC from [Section 6.4](#), one would think low power modes would be a huge help.

As [Chapter 1](#) mentions, DRAMs or disks cannot be accessed in these *inactive low power modes*, so they must be returned to fully active mode to read or write, no matter how low the rate. The pitfall is that the time and energy required to return to fully active mode make inactive low power modes less attractive. [Figure 6.3](#) shows that almost all servers average at least 10% utilization, so long periods of low activity might be expected, but not long periods of inactivity (Lo et al., 2014).

In contrast, processors still run in lower power modes at a small multiple of the regular rate, so *active low power modes* are much easier to use. Note that the time to move to fully active mode for processors is also measured in microseconds, so active low power modes also address the latency concerns about low power modes.

Fallacy *Given improvements in DRAM dependability and the fault tolerance of WSC systems software, there is no need to spend extra for ECC memory in a WSC.*

Because ECC adds 8 bits to every 64 bits of DRAM, potentially a ninth of the DRAM costs could be saved by eliminating error-correcting code (ECC), especially since measurements of DRAM have claimed failure rates of 1000–5000 FIT (failures per billion hours of operation) per megabit ([Tezzaron Semiconductor, 2004](#)).

[Schroeder et al. \(2009\)](#) studied measurements of the DRAMs with ECC protection at the majority of Google’s WSCs, which was surely many hundreds of thousands of servers, over a 2.5-year period. They found 15–25 times higher FIT rates than had been published, or 25,000–70,000 failures per megabit. Failures affected more than 8% of DIMMs, and the average DIMM had 4000 correctable errors and 0.2 uncorrectable errors per year. Measured at the server, about a third experienced DRAM errors each year, with an average of 22,000 correctable errors and 1 uncorrectable error per year. That is, for one-third of the servers, one memory error was corrected every 2.5 h. Note that these systems used the more powerful Chipkill codes rather than the simpler SECDED codes. If the easier scheme had been used, the uncorrectable error rates would have been 4–10 times higher.

In a WSC that had only parity error protection, the servers would have to reboot for each memory parity error. If the reboot time were 5 min, one-third of the machines would spend 20% of their time rebooting! Such behavior would lower the performance of the expensive facility by about 6%. Moreover, these systems would suffer many uncorrectable errors without operators being notified that they occurred.

In the early years, Google used DRAM that did not even have parity protection. In 2000, during testing before shipping the next release of the search index, it started suggesting random documents in response to test queries (Barroso and Hölzle, 2009). The reason was a stuck-at-zero fault in some DRAMs, which corrupted the new index. Google added consistency checks to detect such errors in the future. As WSC grew in size and as ECC DIMMs became more affordable, ECC became the standard in Google WSCs. ECC has the added benefit of making it much easier to find broken DIMMs during repair.

Such data suggest why the Fermi GPU (Chapter 4) adds ECC to its memory where its predecessors didn't even have parity protection. Moreover, these FIT rates cast doubts on efforts to use the Intel Atom processor in a WSC—because of its improved power efficiency—since the chip set did not support ECC DRAM.

Pitfall *Coping effectively with microsecond delays as opposed to nanosecond or millisecond delays.*

Barroso et al. (2017) point out that modern computer systems make it easy for programmers to mitigate latencies in the nanosecond and millisecond timescales (such as cache and DRAM accesses at tens of nanoseconds and disk accesses at a few milliseconds) but that such systems significantly lack support for microsecond-scale events. Programmers get a synchronous interface to the memory hierarchy, with hardware doing heroic work so that such accesses appear consistent and coherent (Chapter 2). Operating systems offer programmers a similar synchronous interface for a disk read, with many lines of OS code enabling the safe switching to another process while waiting for the disk and then returning again to the original process when the data is ready. We need new mechanisms to cope with the microsecond delays of memory technologies like Flash or the fast network interfaces like 100 Gbit/s Ethernet.

Fallacy *Turning off hardware during periods of low activity improves cost-performance of a WSC.*

Figure 6.14 on page 454 shows that the cost of amortizing the power distribution and cooling infrastructure is 50% higher than the entire monthly power bill. Thus, although it certainly would save some money to compact workloads and turn off idle machines, even if half the power were saved, the monthly operational bill would be reduced only by 7%. There would also be practical problems to overcome because the extensive WSC monitoring infrastructure depends on being able to poke equipment and see it respond. Another advantage of energy proportionality and active low power modes is that they are compatible with the WSC monitoring infrastructure, which allows a single operator to be responsible for more than 1000

servers. Note also that preventive maintenance is one of the important tasks that take place during idle time.

The conventional WSC wisdom is to run other valuable tasks during periods of little activity to recoup the investment in power distribution and cooling. A prime example is the batch MapReduce jobs that create indices for search. Another example of getting value from meager utilization is spot pricing on AWS, which the example in [Figure 6.17](#) on page 461 illustrates. AWS users who are flexible about when their tasks are run can save up to a factor of four for computation by letting AWS schedule the tasks more flexibly using spot instances, such as when the WSC would otherwise have low utilization.

6.9

Concluding Remarks

Inheriting the title of building the world's biggest computers, computer architects of WSCs are designing the large part of the future IT that supports the mobile client and IoT devices. Many of us use WSCs many times a day, and the number of times per day and the number of people using WSCs will surely increase in the next decade. Already more than six billion of the seven billion people on the planet have cell phone subscriptions. As these devices become Internet-ready, many more people from around the world will be able to benefit from WSCs.

Moreover, the economies of scale uncovered by WSC have realized the long-dreamed-of goal of computing as a utility. Cloud computing means anyone anywhere with good ideas and business models can tap thousands of servers to deliver their vision almost instantly. Of course, there are important obstacles that could limit the growth of cloud computing around standards, privacy, the rate of growth of Internet bandwidth, and the pitfalls we mention in [Section 6.8](#), but we foresee them being addressed so that cloud computing can continue to flourish.

Among the many attractive features of cloud computing is that it offers economic incentives for conservation. Whereas it is hard to convince cloud computing *providers* to turn off unused equipment to save energy given the cost of the infrastructure investment, it is easy to convince cloud computing *users* to give up idle instances since they are paying for them, whether or not they are doing anything useful. Similarly, charging by use encourages programmers to use computation, communication, and storage efficiently, which can be difficult to encourage without an understandable pricing scheme. The explicit pricing also makes it possible for researchers to evaluate innovations in cost-performance instead of just performance, because costs are now easily measured and believable. Finally, cloud computing means that researchers can evaluate their ideas at the scale of thousands of computers, which in the past only large companies could afford.

We believe that WSCs are changing the goals and principles of server design, just as the needs of mobile clients and IoT are changing the goals and principles of microprocessor design. Both are revolutionizing the software industry, as well. Performance per dollar and performance per joule drive both mobile client hardware and the WSC hardware, and parallelism and domain-specific accelerators are key to delivering on those sets of goals. Architects will play a vital role in both halves of this exciting future world.

Looking forward, the end of Moore's Law and Dennard scaling ([Chapter 1](#)) means that the single-thread performance of the newest processors is not that much faster than their predecessors, which will likely stretch the lifetimes of the servers in the WSCs. Thus, the money formerly spent replacing older servers will instead be used to expand to the cloud, which could mean that the cloud will be even more economically attractive in the next decade than it is today. The Moore's Law era combined with innovations in the design and operation of WSCs caused the performance-cost-energy curve of WSCs to improve continuously. With the end of that glorious era, plus the removal of the largest causes of inefficiency in WSCs, the field will likely need to look to for innovations in computer architecture of the chips that populate the WSC for sustained improvement, which is the topic of the next chapter.

6.10

Historical Perspectives and References

Section M.8 (available online) covers the development of clusters that were the foundation of WSC and of utility computing. (Readers interested in learning more should start with [Barroso et al. \(2013\)](#) and the blog postings of James Hamilton at <http://perspectives.mvdirona.com> plus his talks at the annual Amazon Re-Invent conference.)

Case Studies and Exercises by Parthasarathy Ranganathan

Case Study 1: Total Cost of Ownership Influencing Warehouse-Scale Computer Design Decisions

Concepts illustrated by this case study

- Total Cost of Ownership (TCO)
- Influence of Server Cost and Power on the Entire WSC
- Benefits and Drawbacks of Low-Power Servers

Total cost of ownership is an important metric for measuring the effectiveness of a warehouse-scale computer (WSC). TCO includes both the CAPEX and OPEX described in Section 6.4, and reflects the ownership cost of the entire datacenter to achieve a certain level of performance. In considering different servers, networks, and storage architectures, TCO is often the most important comparison metric used by datacenter owners to decide which options are best; however, TCO is a multidimensional computation that takes into account many different factors. The goal of this case study is to take a detailed look into WSCs, to see how different architectures influence TCO, and to understand how TCO drives operator decisions. This case study will use the numbers from Figures 6.13 and 6.14 and Section 6.4, and assumes that the described WSC achieves the operator's target level of

performance. TCO is often used to compare different server options that have multiple dimensions. The exercises in this case study examine how such comparisons are made in the context of WSCs and the complexity involved in making the decisions.

- 6.1 [5/5/10] <6.2, 6.4> In this chapter, data-level parallelism has been discussed as a way for WSCs to achieve high performance on large problems. Conceivably, even greater performance can be obtained by using high-end servers; however, higher performance servers often come with a nonlinear price increase.
 - a. [5] <6.4> Assuming servers that are 10% faster at the same utilization, but are 20% more expensive, what is the CAPEX for the WSC?
 - b. [5] <6.4> If those servers also use 15% more power, what is the OPEX of the warehouse-scale computer?
 - c. [10] <6.2, 6.4> Given the speed improvement and power increase, what must the cost of the new servers be to be comparable to the original cluster? (*Hint:* Based on this TCO model, you may have to change the critical load of the facility.)
- 6.2 [5/10] <6.4, 6.6, 6.8> To achieve a lower OPEX, one appealing alternative is to use low-power versions of servers to reduce the total electricity required to run the servers; however, similar to high-end servers, low-power versions of high-end components also have nonlinear trade-offs.
 - a. [5] <6.4, 6.6, 6.8> If low-power server options offered 15% lower power at the same performance but are 20% more expensive, are they a good trade-off?
 - b. [10] <6.4, 6.6, 6.8> At what cost do the servers become comparable to the original cluster? What if the price of electricity doubles?
- 6.3 [5/10/15] <6.4, 6.6> Servers that have different operating modes offer opportunities for dynamically running different configurations in the cluster to match workload usage. Use the data in [Figure 6.35](#) for the power/performance modes for a given low-power server.
 - a. [5] <6.4, 6.6> If a server operator decided to save power costs by running all servers at medium performance, how many servers would be needed to achieve the same level of performance?
 - b. [10] <6.4, 6.6> What are the CAPEX and OPEX of such a configuration?

Mode	Performance	Power
High	100%	100%
Medium	75%	60%
Low	59%	38%

Figure 6.35 Power–performance modes for low-power servers.

- c. [15] <6.4, 6.6> If there was an alternative where you could purchase a server that is 20% cheaper but $x\%$ slower and uses $y\%$ less power, find the performance–power curve that provides a TCO comparable to the baseline server.
- 6.4 [Discussion] <6.4> Discuss the trade-offs and benefits of the two options in Exercise 6.3, assuming a constant workload being run on the servers.
- 6.5 [Discussion] <6.2, 6.4> Unlike high-performance computing (HPC) clusters, WSCs often experience significant workload fluctuation throughout the day. Discuss the trade-offs and benefits of the two options in Exercise 6.3, this time assuming a workload that varies.
- 6.6 [Discussion] <6.4, 6.7> The TCO model presented so far abstracts away a significant amount of lower level details. Discuss the impact of these abstractions to the overall accuracy of the TCO model. When are these abstractions safe to make? In what cases would greater detail provide significantly different answers?

Case Study 2: Resource Allocation in WSCs and TCO

Concepts illustrated by this case study

- Server and Power Provisioning within a WSC
- Time Variance of Workloads
- Effects of Variance on TCO

Some of the key challenges to deploying efficient WSCs are provisioning resources properly and utilizing them to their fullest capacity. This problem is complex due to the size of WSCs as well as the potential variance of the workloads being run. The exercises in this case study show how different uses of resources can affect TCO. Assume data from Figures 6.13 and 6.14 as appropriate.

- 6.7 [5/5/10] <6.4> One of the challenges in provisioning a WSC is determining the proper power load, given the facility size. As described in the chapter, nameplate power is often a peak value that is rarely encountered.
 - a. [5] <6.4> Estimate how the per-server TCO changes if the nameplate server power is 200 W and the cost is \$3000.
 - b. [5] <6.4> Also consider a higher power, but cheaper server option whose power is 300 W and costs \$2000.
 - c. [10] <6.4> How does the per-server TCO change if the actual average power usage of the servers is only 70% of the nameplate power?
- 6.8 [15/10] <6.2, 6.4> One assumption in the TCO model is that the critical load of the facility is fixed, and the amount of servers fits that critical load. In reality, due to the variations of server power based on load, the critical power used by a facility can vary at any given time. Operators must initially provision the datacenter based on its critical power resources and an estimate of how much power is used by the datacenter components.

- a. [15] <6.2, 6.4> Extend the TCO model to initially provision a WSC based on a server with a nameplate power of 300 W, but also calculate the actual monthly critical power used and TCO assuming the server averages 40% utilization and so consumes only 225 W. How much capacity is left unused?
 - b. [10] <6.2, 6.4> Repeat this exercise with a 500-W server that averages 20% utilization and consumes only 300 W.
- 6.9 [10] <6.4, 6.5> WSCs are often used in an interactive manner with end users, as mentioned in Section 6.5. This interactive usage often leads to time-of-day fluctuations, with peaks correlating to specific time periods. For example, for Netflix rentals there is a peak during the evening periods of 8–10 p.m.; the entirety of these time-of-day effects is significant. Compare the per-server TCO of a datacenter with a capacity to match the utilization at 4 a.m. compared to 9 p.m.
- 6.10 [Discussion/15] <6.4, 6.5> Discuss some options to better utilize the excess servers during the off-peak hours or find ways to save costs. Given the interactive nature of WSCs, what are some of the challenges to aggressively reducing power usage?
- 6.11 [Discussion/25] <6.4, 6.6, 6.8> Propose one possible way to improve TCO by focusing on reducing server power. What are the challenges to evaluating your proposal? Estimate the TCO improvements based on your proposal. What are some advantages and drawbacks?

Exercises

- 6.12 [10/10/10] <6.1, 6.2> One of the important enablers of WSC is ample request-level parallelism, in contrast to instruction- or thread-level parallelism. This question explores the implication of different types of parallelism on computer architecture and system design.
- a. [10] <6.1> Discuss scenarios where improving the instruction- or thread-level parallelism would provide greater benefits than those achievable through request-level parallelism.
 - b. [10] <6.1, 6.2> What are the software design implications of increasing request-level parallelism?
 - c. [10] <6.1, 6.2> What are potential drawbacks of increasing request-level parallelism?
- 6.13 [Discussion/15/15] <6.2, 6.3> When a cloud computing service provider receives jobs consisting of multiple Virtual Machines (VMs) (e.g., a MapReduce job), many scheduling options exist. The VMs can be scheduled in a round-robin manner to spread across all available processors and servers, or they can be consolidated to use as few processors as possible. Using these scheduling options, if a job with 24 VMs was submitted and 30 processors were available in the cloud (each able to run up to 3 VMs), round-robin would use 24 processors, while consolidated scheduling would use 8 processors. The scheduler can also find available processor cores at different scopes: socket, server, rack, and an array of racks.

- a. [Discussion] <6.2, 6.3> Assuming that the submitted jobs are all compute-heavy workloads, possibly with different memory bandwidth requirements, what are the pros and cons of round-robin versus consolidated scheduling in terms of power and cooling costs, performance, and reliability?
 - b. [15] <6.2, 6.3> Assuming that the submitted jobs are all I/O-heavy workloads, what are the pros and cons of round-robin versus consolidated scheduling, at different scopes?
 - c. [15] <6.2, 6.3> Assuming that the submitted jobs are network-heavy workloads, what are the pros and cons of round-robin versus consolidated scheduling, at different scopes?
- 6.14 [15/15/10/10] <6.2, 6.3> MapReduce enables large amounts of parallelism by having data-independent tasks run on multiple nodes, often using commodity hardware; however, there are limits to the level of parallelism. For example, for redundancy MapReduce will write data blocks to multiple nodes, consuming disk and, potentially, network bandwidth. Assume a total dataset size of 300 GB, a network bandwidth of 1 Gb/s, a 10 s/GB map rate, and a 20 s/GB reduce rate. Also assume that 30% of the data must be read from remote nodes, and each output file is written to two other nodes for redundancy. Use Figure 6.6 for all other parameters.
- a. [15] <6.2, 6.3> Assume that all nodes are in the same rack. What is the expected runtime with 5 nodes? 10 nodes? 100 nodes? 1000 nodes? Discuss the bottlenecks at each node size.
 - b. [15] <6.2, 6.3> Assume that there are 40 nodes per rack and that any remote read/write has an equal chance of going to any node. What is the expected runtime at 100 nodes? 1000 nodes?
 - c. [10] <6.2, 6.3> An important consideration is minimizing data movement as much as possible. Given the significant slowdown of going from local to rack to array accesses, software must be strongly optimized to maximize locality. Assume that there are 40 nodes per rack, and 1000 nodes are used in the MapReduce job. What is the runtime if remote accesses are within the same rack 20% of the time? 50% of the time? 80% of the time?
 - d. [10] <6.2, 6.3> Given the simple MapReduce program in Section 6.2, discuss some possible optimizations to maximize the locality of the workload.
- 6.15 [20/20/10/20/20/20] <6.2, 6.3> WSC programmers often use data replication to overcome failures in the software. Hadoop HDFS, for example, employs three-way replication (one local copy, one remote copy in the rack, and one remote copy in a separate rack), but it's worth examining when such replication is needed.
- a. [20] <6.2> Let us assume that Hadoop clusters are relatively small, with 10 nodes or less, and with dataset sizes of 10 TB or less. Using the failure frequency data in Figure 6.1, what kind of availability does a 10-node Hadoop cluster have with one-, two-, and three-way replications?
 - b. [20] <6.2> Assuming the failure data in Figure 6.1 and a 1000-node Hadoop cluster, what kind of availability does it have with one-, two-, and three-way replications? What can you reason about the benefits of replication, at scale?

- c. [10] <6.2, 6.3> The relative overhead of replication varies with the amount of data written per local compute hour. Calculate the amount of extra I/O traffic and network traffic (within and across rack) for a 1000-node Hadoop job that sorts 1 PB of data, where the intermediate results for data shuffling are written to the HDFS.
 - d. [20] <6.2, 6.3> Using Figure 6.6, calculate the time overhead for two- and three-way replications. Using the failure rates shown in Figure 6.1, compare the expected execution times for no replication versus two- and three-way replications.
 - e. [20] <6.2, 6.3> Now consider a database system applying replication on logs, assuming each transaction on average accesses the hard disk once and generates 1 KB of log data. Calculate the time overhead for two- and three-way replications. What if the transaction is executed in-memory and takes 10 μ s?
 - f. [20] <6.2, 6.3> Now consider a database system with ACID consistency that requires two network round trips for two-phase commitment. What is the time overhead for maintaining consistency as well as replications?
- 6.16 [15/15/20/Discussion] <6.1, 6.2, 6.8> Although request-level parallelism allows many machines to work on a single problem in parallel, thereby achieving greater overall performance, one of the challenges is how to avoid dividing the problem too finely. If we look at this problem in the context of service level agreements (SLAs), using smaller problem sizes through greater partitioning can require increased effort to achieve the target SLA. Assume an SLA of 95% of queries respond at 0.5 s or faster, and a parallel architecture similar to MapReduce that can launch multiple redundant jobs to achieve the same result. For the following questions, assume the query-response time curve shown in Figure 6.36. The curve shows the latency of response, based on the number of queries per second, for a baseline server as well as a “small” server that uses a slower processor model.

Figure 6.36 Query-response time curve.

- a. [15] <6.1, 6.2, 6.8> How many servers are required to achieve this SLA, assuming the query-response time curve shown in Figure 6.36 and the WSC receiving 30,000 queries per second? How many “small” servers are required to achieve this SLA, given this response-time probability curve? Looking only at server costs, how much cheaper must the “small” servers be than the normal servers to achieve a cost advantage for the target SLA?
 - b. [15] <6.1, 6.2, 6.8> Often, “small” servers are also less reliable due to cheaper components. Using the numbers from Figure 6.1, assume that the number of events due to flaky machines and bad memories increases by 30%. How many “small” servers are required now? How much cheaper must those servers be than the standard servers?
 - c. [20] <6.1, 6.2, 6.8> Now assume a batch processing environment. The “small” servers provide 30% of the overall performance of the regular servers. Still assuming the reliability numbers from Exercise 6.15 part (b), how many “small” nodes are required to provide the same expected throughput of a 2400-node array of standard servers, assuming perfect linear scaling of performance to node size and an average task length of 10 min per node? What if the scaling is 85%? 60%?
 - d. [Discussion] <6.1, 6.2, 6.8> Often the scaling is not a linear function, but instead a logarithmic function. A natural response may be instead to purchase larger nodes that have more computational power per node to minimize the array size. Discuss some of the trade-offs with this architecture.
- 6.17 [10/10/15/Discussion] <6.3, 6.8> One trend in high-end servers is toward the inclusion of nonvolatile flash memory in the memory hierarchy, either through solid-state disks (SSDs) or PCI Express-attached cards. Typical SSDs have a bandwidth of 250 MB/s and latency of 75 μ s, whereas PCIe cards have a bandwidth of 600 MB/s and latency of 35 μ s.
- a. [10] Take Figure 6.7 and include these points in the local server hierarchy. Assuming that identical performance scaling factors like DRAM are accessed at different hierarchy levels, how do these flash memory devices compare when accessed across the rack? Across the array?
 - b. [10] Discuss some software-based optimizations that can utilize the new level of the memory hierarchy.
 - c. [15] As discussed in “Fallacies and Pitfalls” (Section 6.8), replacing all disks with SSDs is not necessarily a cost-effective strategy. Consider a WSC operator that uses it to provide cloud services. Discuss some scenarios where using SSDs or other flash memory would make sense.
 - d. [Discussion] Recently, some vendors have discussed new memory technologies that are much faster than flash. As an example, look up the specifications for Intel 3D X-point memory and discuss how it would factor in Figure 6.7.

- 6.18 [20/20/Discussion] <6.3> *Memory Hierarchy*: Caching is heavily used in some WSC designs to reduce latency, and there are multiple caching options to satisfy varying access patterns and requirements.
- [20] Let's consider the design options for streaming rich media from the Web (e.g., Netflix). First we need to estimate the number of videos, number of encode formats per video, and concurrent viewing users. Assume a streaming video provider that has 12,000 titles for online streaming, each title having at least four encode formats (at 500, 1000, 1600, and 2200 kbps). Let's also assume that there are 100,000 concurrent viewers for the entire site, and an average video is 75 min long (accounting for both 30-min shows and 2-h videos). Estimate the total storage capacity, I/O and network bandwidths, and video-streaming-related computation requirements.
 - [20] What are the access patterns and reference locality characteristics per user, per video, and across all videos? (*Hint*: Random versus sequential, good versus poor temporal and spatial locality, relatively small versus large working set size.)
 - [Discussion] What movie storage options exist by using DRAM, SSD, and hard drives? Compare them in performance and TCO. Would new memory technologies like those in Problem 6.17(d) be useful?
- 6.19 [Discussion/20/Discussion/Discussion] <6.3> Consider a social networking website with 100 million active users posting updates about themselves (in text and pictures) as well as browsing and interacting with updates in their social networks. To provide low latency, Facebook and many other websites use memcached as a caching layer before the backend storage/database tiers. Assume that at any given time the average user is browsing megabytes of content, and on any given day the average user uploads megabytes of content.
- [20] For the social networking website discussed here, how much DRAM is needed to host its working set? Using servers each having 96 GB DRAM, estimate how many local versus remote memory accesses are needed to generate a user's home page?
 - [Discussion] Now consider two candidate memcached server designs, one using conventional Xeon processors and the other using smaller cores, such as Atom processors. Given that memcached requires large physical memory but has low CPU utilization, what are the pros and cons of these two designs?
 - [Discussion] Today's tight coupling between memory modules and processors often requires an increase in CPU socket count in order to provide large memory support. List other designs to provide large physical memory without proportionally increasing the number of sockets in a server. Compare them based on performance, power, costs, and reliability.
 - [Discussion] The same user's information can be stored in both the memcached and storage servers, and such servers can be physically hosted in different ways. Discuss the pros and cons of the following server layout in the WSC: (1)

memcached collocated on the same storage server, (2) memcached and storage servers on separate nodes in the same rack, or (3) memcached servers on the same racks and storage servers collocated on separate racks.

- 6.20 [5/5/10/10/Discussion/Discussion/Discussion] <6.3, 6.5, 6.6> *Datacenter Networking*: MapReduce and WSC are a powerful combination to tackle large-scale data processing. For this problem, we will assume we sort one petabyte (1 PB) of records in 6 h using 4000 servers and 48,000 hard drives (Google discussed doing this in 2008).
- [5] Derive disk bandwidth from Figure 6.6 and associated text. How many seconds does it take to read the data into main memory and write the sorted results back?
 - [5] Assuming each server has two 1 Gb/s Ethernet network interface cards (NICs) and the WSC switch infrastructure is oversubscribed by a factor of 4, how many seconds does it take to shuffle the entire dataset across 4000 servers?
 - [10] Assuming network transfer is the performance bottleneck for petabyte sort, can you estimate what oversubscription ratio Google has in its datacenter?
 - [10] Now let's examine the benefits of having 10 Gb/s Ethernet without oversubscription—for example, using a 48-port 10 Gb/s Ethernet (this was used by the 2010 Indy sort benchmark winner TritonSort). How long does it take to shuffle 1 PB of data?
 - [Discussion] Compare the two approaches here: (1) the massive scale-out approach with high network oversubscription ratio, and (2) a relatively small-scale system with a high-bandwidth network. What are their potential bottlenecks? What are their advantages and disadvantages, in terms of scalability and TCO?
 - [Discussion] Sort and many important scientific computing workloads are communication-heavy, while many other workloads are not. List three example workloads that do not benefit from high-speed networking. What EC2 instances would you recommend to use for these two classes of workloads?
 - [Discussion] Look up the various benchmarks in www.sortbenchmark.org and recent winners in each category. How do these results match the insights from the discussion in part (e) above? How does the cloud instance used for the most recent winner of CloudSort compare with your answer in part (f) above?
- 6.21 [10/25/Discussion] <6.4, 6.6> Because of the massive scale of WSCs, it is very important to properly allocate network resources based on the workloads that are expected to be run. Different allocations can have significant impacts on both the performance and total cost of ownership.
- [10] Using the numbers in the spreadsheet detailed in Figure 6.13, what is the oversubscription ratio at each access-layer switch? What is the impact on TCO if the oversubscription ratio is cut in half? What if it is doubled?
 - [25] Reducing the oversubscription ratio can potentially improve performance if a workload is network-limited. Assume a MapReduce job that uses 120

servers and reads 5 TB of data. Assume the same ratio of read/intermediate/output data as in Figure 6.2, Sep-09, and use Figure 6.6 to define the bandwidths of the memory hierarchy. When reading data, assume that 50% of data is read from remote disks; of that, 80% is read from within the rack and 20% is read from within the array. For intermediate data and output data, assume that 30% of the data uses remote disks; of that, 90% is within the rack and 10% is within the array. What is the overall performance improvement when reducing the oversubscription ratio by half? What is the performance if the oversubscription ratio is doubled? Calculate the TCO in each case.

- c. [Discussion] We are seeing the trend to more cores per system. We are also seeing the increasing adoption of optical communication (with potentially higher bandwidth and improved energy efficiency). How do you think these and other emerging technology trends will affect the design of future WSCs?
- 6.22 [5/15/15/20/25/Discussion] <6.5> *Realizing the Capability of the Cloud*: Imagine you are the site operation and infrastructure manager of an Alexa.com top site and are considering using Amazon Web Services (AWS). What factors do you need to consider in determining whether to migrate to AWS? What services and instance types could you use, and how much cost could you save? You can use Alexa and site traffic information (e.g., Wikipedia provides page view stats) to estimate the amount of traffic received by a top site, or you can take concrete examples from the Web, such as the following example: <http://2bits.com/sites/2bits.com/files/drupal-single-server-2.8-million-page-views-a-day.pdf>. The slides describe an Alexa #3400 site that receives 2.8 million page views per day, using a single server. The server has two quad-core Xeon 2.5 GHz processors with 8 GB DRAM and three 15 K RPM SAS hard drives in a RAID1 configuration, and it costs about \$400 per month. The site uses caching heavily, and the CPU utilization ranges from 50% to 250% (roughly 0.5–2.5 cores busy).
- a. [5] Looking at the available EC2 instances (<http://aws.amazon.com/ec2/instance-types/>), what instance types match or exceed the current server configuration?
 - b. [15] Looking at the EC2 pricing information (<http://aws.amazon.com/ec2/pricing/>), select the most cost-efficient EC2 instances (combinations allowed) to host the site on AWS. What is the monthly cost for EC2?
 - c. [15] Now add the costs for IP address and network traffic to the equation, and suppose the site transfers 100 GB/day in and out on the Internet. What is the monthly cost for the site now?
 - d. [20] AWS also offers a micro instance for free for 1 year to new customers and 15 GB bandwidth each for traffic going in and out across AWS. Based on your estimation of peak and average traffic from your department Web server, can you host it for free on AWS?

- e. [25] Based on the service characteristics, if a much larger site like [Netflix.com](https://www.netflix.com) migrates its streaming and encoding infrastructure to AWS, what AWS services could be used by Netflix and for what purposes?
 - f. [Discussion] Look at similar offerings from other cloud providers (Google, Microsoft, Alibaba, etc.). How do the answers to parts (a)–(e) change?
 - g. [Discussion] “Serverless computing” allows you to build and run higher-level applications and services without thinking about specific servers. Examples include AWS Lambda, Google Cloud Functions, Microsoft Azure Functions, etc. Continuing to wear your site operation and infrastructure manager hat, when would you consider serverless computing?
- 6.23 [Discussion/Discussion/20/20/Discussion] <6.4, 6.8> Figure 6.12 shows the impact of user perceived response time on revenue, and motivates the need to achieve high-throughput while maintaining low latency.
- a. [Discussion] Taking Web search as an example, what are the possible ways of reducing query latency?
 - b. [Discussion] What monitoring statistics can you collect to help understand where time is spent? How do you plan to implement such a monitoring tool?
 - c. [20] Assuming that the number of disk accesses per query follows a normal distribution, with an average of 2 and standard deviation of 3, what kind of disk access latency is needed to satisfy a latency SLA of 0.1 s for 95% of the queries?
 - d. [20] In-memory caching can reduce the frequencies of long-latency events (e.g., accessing hard drives). Assuming a steady-state hit rate of 40%, hit latency of 0.05 s, and miss latency of 0.2 s, does caching help meet a latency SLA of 0.1 s for 95% of the queries?
 - e. [Discussion] When can cached content become stale or even inconsistent? How often can this happen? How can you detect and invalidate such content?
- 6.24 [15/15/20/Discussion] <6.4, 6.6> The efficiency of typical power supply units (PSUs) varies as the load changes; for example, PSU efficiency can be about 80% at 40% load (e.g., output 40 W from a 100-W PSU), 75% when the load is between 20% and 40%, and 65% when the load is below 20%.
- a. [15] Assume a power-proportional server whose actual power is proportional to CPU utilization, with a utilization curve as shown in Figure 6.3. What is the average PSU efficiency?
 - b. [15] Suppose the server employs $2N$ redundancy for PSUs (i.e., doubles the number of PSUs) to ensure stable power when one PSU fails. What is the average PSU efficiency?
 - c. [20] Blade server vendors use a shared pool of PSUs not only to provide redundancy but also to dynamically match the number of PSUs to the server’s actual power consumption. The HP c7000 enclosure uses up to six PSUs for a total of 16 servers. In this case, what is the average PSU efficiency for the enclosure of server with the same utilization curve?

- d. [Discussion] Consider the impact of the different efficiency numbers in the context of the broader TCO discussions in Figures 6.13 and 6.14: how do the different design impact the total TCO? Given these, how would you optimize designs for future warehouse-scale computers?
- 6.25 [5/Discussion/10/15/Discussion/Discussion/Discussion] $\langle 6.4, 6.8 \rangle$ *Power stranding* is a term used to refer to power capacity that is provisioned but not used in a datacenter. Consider the data presented in Figure 6.37 [Fan, Weber, and Barroso, 2007] for different groups of machines. (Note that what this paper calls a “cluster” is what we have referred to as an “array” in this chapter.)
- a. [5] What is the stranded power at (1) the rack level, (2) the power distribution unit level, and (3) the array (cluster) level? What are the trends with oversubscription of power capacity at larger groups of machines?
- b. [Discussion] What do you think causes the differences between power stranding at different groups of machines?
- c. [10] Consider an array-level collection of machines where the total machines never use more than 72% of the aggregate power (this is sometimes also referred to as the ratio between the peak-of-sum and sum-of-peaks usage). Using the cost model in the case study, compute the cost savings from comparing a datacenter provisioned for peak capacity and one provisioned for actual use.
- d. [15] Assume that the datacenter designer chose to include additional servers at the array level to take advantage of the stranded power. Using the example configuration and assumptions in part (a), compute how many more servers can now be included in the warehouse-scale computer for the same total power provisioning.
- e. [Discussion] What is needed to make the optimization of part (d) work in a real-world deployment? (*Hint*: Think about what needs to happen to cap power in the rare case when all the servers in the array are used at peak power.)

Figure 6.37 Cumulative distribution function (CDF) of a real datacenter.

- f. [Discussion] Two kinds of policies can be envisioned to manage power caps [Ranganathan et al., 2006]: (1) preemptive policies where power budgets are predetermined (“don’t assume you can use more power; ask before you do!”) or (2) reactive policies where power budgets are throttled in the event of a power budget violation (“use as much power as needed until told you can’t!”). Discuss the trade-offs between these approaches and when you would use each type.
 - g. [Discussion] What happens to the total stranded power if systems become more energy-proportional (assume workloads similar to that of Figure 6.4)?
- 6.26 [5/20/Discussion] <6.4, 6.7> Section 6.7 discussed the use of per-server battery sources in the Google design. Let us examine the consequences of this design.
- a. [5] Assume that the use of a battery as a mini-server-level UPS is 99.99% efficient and eliminates the need for a facility-wide UPS that is only 92% efficient. Assume that substation switching is 99.7% efficient and that the efficiency for the PDU, step-down stages, and other electrical breakers are 98%, 98%, and 99%, respectively. Calculate the overall power infrastructure efficiency improvements from using a per-server battery backup.
 - b. [20] Assume that the UPS is 10% of the cost of the IT equipment. Using the rest of the assumptions from the cost model in the case study, what is the break-even point for the costs of the battery (as a fraction of the cost of a single server) at which the total cost of ownership for a battery-based solution is better than that for a facility-wide UPS?
 - c. [Discussion] What are the other trade-offs between these two approaches? In particular, how do you think the manageability and failure model will change across these two different designs?
- 6.27 [5/5/Discussion] <6.4> For this exercise, consider a simplified equation for the total operational power of a WSC as follows:
- $$\text{Total operational power} = (1 + \text{Cooling inefficiency multiplier}) * \text{IT equipment power}.$$
- a. [5] Assume an 8 MW datacenter at 80% power usage, electricity costs of \$0.10 per kilowatt-hour, and a cooling-inefficiency multiplier of 0.8. Compare the cost savings from (1) an optimization that improves cooling efficiency by 20%, and (2) an optimization that improves the energy efficiency of the IT equipment by 20%.
 - b. [5] What is the percentage improvement in IT equipment energy efficiency needed to match the cost savings from a 20% improvement in cooling efficiency?
 - c. [Discussion/10] What conclusions can you draw about the relative importance of optimizations that focus on server energy efficiency and cooling energy efficiency?
- 6.28 [5/5/Discussion] <6.4> As discussed in this chapter, the cooling equipment in WSCs can themselves consume a lot of energy. Cooling costs can be lowered

by proactively managing temperature. Temperature-aware workload placement is one optimization that has been proposed to manage temperature to reduce cooling costs. The idea is to identify the cooling profile of a given room and map the hotter systems to the cooler spots, so that at the WSC level the requirements for overall cooling are reduced.

- a. [5] The coefficient of performance (COP) of a computer room air conditioning unit (CRAC) is a measure of its efficiency, and is defined as the ratio of heat removed (Q) to the amount of work necessary (W) to remove that heat. The COP of a CRAC unit increases with the temperature of the air the CRAC unit pushes into the plenum. If air returns to the CRAC unit at 20°C and we remove 10 KW of heat with a COP of 1.9, how much energy do we expend in the CRAC unit? If it takes a COP of 3.1 to cool the same volume of air, but the air is returned at 25°C, how much energy do we now expend in the CRAC unit?
 - b. [5] Assume a workload distribution algorithm is able to match the hot workloads well with the cool spots to allow the computer room air-conditioning (CRAC) unit to be run at a higher temperature to improve cooling efficiencies like in the exercise above. What is the power savings between the two cases described above?
 - c. [Discussion] Given the scale of WSC systems, power management can be a complex, multifaceted problem. Optimizations to improve energy efficiency can be implemented in hardware and in software, at the system level, and at the cluster level for the IT equipment or the cooling equipment, etc. It is important to consider these interactions when designing an overall energy-efficiency solution for the WSC. Consider a consolidation algorithm that looks at server utilization and consolidates different workload classes on the same server to increase server utilization (this can potentially have the server operating at a higher energy efficiency if the system is not energy-proportional). How would this optimization interact with a concurrent algorithm that tried to use different power states (see ACPI, Advanced Configuration Power Interface, for some examples)? What other examples can you think of where multiple optimizations can potentially conflict with one another in a WSC? How would you solve this problem?
- 6.29 [5/10/15/20] <6.2, 6.6> Energy proportionality (sometimes also referred to as energy scale-down) is the attribute of the system to consume no power when idle, but more importantly gradually consume more power *in proportion* to the activity level and work done. In this exercise, we will examine the sensitivity of energy consumption to different energy proportionality models. In the exercises below, unless otherwise mentioned, use the data in Figure 6.4 as the default.
- a. [5] A simple way to reason about energy proportionality is to assume linearity between activity and power usage. Using just the peak power and idle power data from Figure 6.4 and a linear interpolation, plot the energy-efficiency trends across varying utilizations. (Energy efficiency is expressed as performance per watt.) What happens if idle power (at 0% activity) is half of what is assumed in Figure 6.4? What happens if idle power is zero?

- b. [10] Plot the energy-efficiency trends across varying activities, but use the data from column 3 of Figure 6.4 for power variation. Plot the energy efficiency assuming that the idle power (alone) is half of what is assumed in Figure 6.4. Compare these plots with the linear model in the previous exercise. What conclusions can you draw about the consequences of focusing purely on idle power alone?
- c. [15] Assume the system utilization mix in column 7 of Figure 6.4. For simplicity, assume a discrete distribution across 1000 servers, with 109 servers at 0% utilization, 80 servers at 10% utilization, etc. Compute the total performance and total energy for this workload mix using the assumptions in part (a) and part (b).
- d. [20] One could potentially design a system that has a sublinear power versus load relationship in the region of load levels between 0% and 50%. This would have an energy-efficiency curve that peaks at lower utilizations (at the expense of higher utilizations). Create a new version of column 3 from Figure 6.4 that shows such an energy-efficiency curve. Assume the system utilization mix in column 7 of Figure 6.4. For simplicity, assume a discrete distribution across 1000 servers, with 109 servers at 0% utilization, 80 servers at 10% utilizations, etc. Compute the total performance and total energy for this workload mix.
- 6.30 [15/20/20] <6.2, 6.6> This exercise illustrates the interactions of energy proportionality models with optimizations such as server consolidation and energy-efficient server designs. Consider the scenarios shown in Figures 6.38 and 6.39.
- a. [15] Consider two servers with the power distributions shown in Figure 6.38: case A (the server considered in Figure 6.4) and case B (a less energy-proportional but more energy-efficient server than case A). Assume the system utilization mix in column 7 of Figure 6.4. For simplicity, assume a discrete distribution across 1000 servers, with 109 servers at 0% utilization, 80 servers at 10% utilizations, etc., as

Activity (%)	0	10	20	30	40	50	60	70	80	90	100
Power, case A (W)	181	308	351	382	416	451	490	533	576	617	662
Power, case B (W)	250	275	325	340	395	405	415	425	440	445	450

Figure 6.38 Power distribution for two servers.

Activity (%)	0	10	20	30	40	50	60	70	80	90	100
No. servers, case A and B	109	80	153	246	191	115	51	21	15	12	8
No. servers, case C	504	6	8	11	26	57	95	123	76	40	54

Figure 6.39 Utilization distributions across cluster, without and with consolidation.

shown in row 1 of Figure 6.39. Assume performance variation based on column 2 of Figure 6.4. Compare the total performance and total energy for this workload mix for the two server types.

- b. [20] Consider a cluster of 1000 servers with data similar to the data shown in Figure 6.4 (and summarized in the first rows of Figures 6.38 and 6.39). What are the total performance and total energy for the workload mix with these assumptions? Now assume that we were able to consolidate the workloads to model the distribution shown in case C (second row of Figure 6.39). What are the total performance and total energy now? How does the total energy compare with a system that has a linear energy-proportional model with idle power of zero watts and peak power of 662 W?
 - c. [20] Repeat part (b), but with the power model of server B, and compare with the results of part (a).
- 6.31 [10/Discussion] <6.2, 6.4, 6.6> *System-Level Energy Proportionality Trends*: Consider the following breakdowns of the power consumption of a server:
- CPU, 50%; memory, 23%; disks, 11%; networking/other, 16%
 CPU, 33%; memory, 30%; disks, 10%; networking/other, 27%
- a. [10] Assume a dynamic power range of $3.0\times$ for the CPU (i.e., the power consumption of the CPU at idle is one-third that of its power consumption at peak). Assume that the dynamic range of the memory systems, disks, and the networking/other categories above are, respectively, $2.0\times$, $1.3\times$, and $1.2\times$. What is the overall dynamic range for the total system for the two cases?
 - b. [Discussion/10] What can you learn from the results of part (a)? How would we achieve better energy proportionality at the system level? (*Hint*: Energy proportionality at a system level cannot be achieved through CPU optimizations alone, but instead requires improvement across all components.)
- 6.32 [30] <6.4> Pitt Turner IV et al. [2008] presented a good overview of datacenter tier classifications. Tier classifications define site infrastructure performance. For simplicity, consider the key differences as shown in Figure 6.40 (adapted from Pitt Turner IV et al. [2008]). Using the TCO model in the case study as a guiding framework, compare the cost implications of the different tiers shown.
- 6.33 [Discussion] <6.4> Based on the observations in Figures 6.12 and 6.13, what can you say qualitatively about the trade-offs between revenue loss from downtime and costs incurred for uptime?
- 6.34 [15/Discussion] <6.4> Some recent studies have defined a metric called TPUE, which stands for “true PUE” or “total PUE.” TPUE is defined as $PUE * SPUE$. PUE, the power utilization effectiveness, is defined in Section 6.4 as the ratio of the total facility power over the total IT equipment power. SPUE, or server PUE, is a new metric analogous to PUE, but instead applied to computing equipment. SPUE is defined as the ratio of total server input power to its useful power, where useful power is defined as the power consumed by the electronic components

Tier 1	Single path for power and cooling distributions, without redundant components	99.0%
Tier 2	($N + 1$) redundancy = two power and cooling distribution paths	99.7%
Tier 3	($N + 2$) redundancy = three power and cooling distribution paths for uptime even during maintenance	99.98%
Tier 4	Two active power and cooling distribution paths, with redundant components in each path, to tolerate any single equipment failure without impacting the load	99.995%

Figure 6.40 Overview of data center tier classifications. (Adapted from Pitt Turner IV et al. [2008].)

directly involved in the computation: motherboard, disks, CPUs, DRAM, I/O cards, and so on. In other words, the SPUE metric captures inefficiencies associated with the power supplies, voltage regulators, and fans housed on a server.

- a. [15] <6.4> Consider a design that uses a higher supply temperature for the computer room air conditioning (CRAC) units. The efficiency of the CRAC unit is approximately a quadratic function of the temperature, and this design therefore improves the overall PUE, let's assume by 7%. (Assume baseline PUE of 1.7.) However, the higher temperature at the server level triggers the on-board fan controller to operate the fan at much higher speeds. The fan power is a cubic function of speed, and the increased fan speed leads to a degradation of SPUE. Assume a fan power model:

$$\text{Fan power} = 284 * ns * ns * ns - 75 * ns * ns,$$

where ns is the normalized fan speed = fan speed in rpm/18,000 and a baseline server power of 350 W. Compute the SPUE if the fan speed increases from (1) 10,000–12,500 rpm and (2) 10,000–18,000 rpm. Compare the PUE and TPUE in both these cases. (For simplicity, ignore the inefficiencies with power delivery in the SPUE model.)

- b. [Discussion] Part (a) illustrates that, while PUE is an excellent metric to capture the overhead of the facility, it does not capture the inefficiencies within the IT equipment itself. Can you identify another design where changes to the TPUE are potentially lower than the changes to traditional PUE? (*Hint*: See Exercise 6.26.)
- 6.35 [Discussion/30/Discussion] <6.2> Two benchmarks provide a good starting point for energy-efficiency accounting in servers—the SPECpower_ssj2008 benchmark (available at http://www.spec.org/power_ssj2008/) and the JouleSort metric (available at <http://sortbenchmark.org/>).
- a. [Discussion] <6.2> Look up the descriptions of the two benchmarks. How are they similar? How are they different? What would you do to improve these benchmarks to better address the goal of improving WSC energy efficiency?

- b. [30] <6.2> JouleSort measures the total system energy to perform an out-of-core sort and attempts to derive a metric that enables the comparison of systems ranging from embedded devices to supercomputers. Look up the description of the JouleSort metric at <http://sortbenchmark.org>. Download a publicly available version of the sort algorithm and run it on different classes of machines—a laptop, a PC, a mobile phone, etc.—or with different configurations. What can you learn from the JouleSort ratings for different setups?
 - c. [Discussion] <6.2> Consider the system with the best JouleSort rating from your experiments above. How would you improve the energy efficiency? For example, try rewriting the sort code to improve the JouleSort rating. What does running sort in the cloud do to energy efficiency?
- 6.36 [10/10/15] <6.1, 6.2> Figure 6.1 is a listing of outages in an array of servers. When dealing with the large scale of WSCs, it is important to balance cluster design and software architectures to achieve the required uptime without incurring significant costs. This question explores the implications of achieving availability through hardware only.
 - a. [10] <6.1, 6.2> Assuming that an operator wishes to achieve 95% availability through server hardware improvements alone, how many events of each type would have to be reduced? For now, assume that individual server crashes are completely handled through redundant machines.
 - b. [10] <6.1, 6.2> How does the answer to part (a) change if the individual server crashes are handled by redundancy 50% of the time? 20% of the time? None of the time?
 - c. [15] <6.1, 6.2> Discuss the importance of software redundancy to achieving a high level of availability. If a WSC operator considered buying machines that were cheaper but 10% less reliable, what implications would this have on the software architecture? What are the challenges associated with software redundancy?
 - d. [Discussion] <6.1> Discuss the importance of eventual consistency in how warehouse-scale computers can scale.
- 6.37 [15] <6.1, 6.8> Look up the current prices of standard DDR4 DRAM versus DDR4 DRAM that has error-correcting code (ECC). What is the increase in price per bit for achieving the higher reliability that ECC provides? Using the DRAM prices alone, and the data provided in Section 6.8, what is the uptime per dollar of a WSC with non-ECC versus ECC DRAM?
- 6.38 [5/Discussion] <6.1, 6.8> *WSC Reliability and Manageability Concerns:*
 - a. [5] Consider a cluster of servers costing \$2000 each. Assuming an annual failure rate of 5%, an average of an hour of service time per repair, and replacement parts requiring 10% of the system cost per failure, what is the annual maintenance cost per server? Assume an hourly rate of \$100 per hour for a service technician.

- b. [Discussion] Comment on the differences between this manageability model versus that in a traditional enterprise datacenter with a large number of small- or medium-sized applications each running on its own dedicated hardware infrastructure.
 - c. [Discussion] Discuss the trade-offs in having heterogeneous machines in a warehouse-scale computer.
- 6.39 [Discussion] <6.4, 6.7, 6.8> The OpenCompute project at www.opencompute.org provides a community to design and share efficient designs for warehouse-scale computers. Look at some of the recently proposed designs. How do they compare with the design trade-offs discussed in this chapter? How do the designs differ from the Google case study discussed in Section 6.7?
- 6.40 [15/15] <6.3, 6.4, 6.5> Assume that the MapReduce job from Page #438 in Section 6.2 is executing a task with 2^{40} bytes of input data, 2^{37} bytes of intermediate data, and 2^{30} bytes of output data. This job is entirely memory/storage bound, so its performance can be quantified by the DRAM/Disk bandwidth of Figure 6.6.
 - a. How much does the job cost to run on m4.16xlarge and m4.large in Figure 6.15? Which EC2 instance provides better performance? Which EC2 instance provides better cost?
 - b. How much would the job cost if an SSD was added to the system, as in m3.medium? How do the performance and cost of m3.medium compare with the best instance from part (a) above?
- 6.41 <6.1, 6.4> [5/5/10/Discussion] Imagine you have created a web service that runs very well (responds within 100 ms latency) 99% of the time, and has performance issues 1% of the time (maybe the CPU went into a lower power state and the response took 1000 ms, etc.).
 - a. [5] Your service grows popular, and you now have 100 servers and your computation has to touch all these servers to handle the user request. What is the percentage of time your query is likely to have a slow response time, across 100 servers?
 - b. [5] Instead of “two nines” (99%) single server latency SLA, how many “nines” do we need to have for the single server latency SLA so that the cluster latency SLA has bad latencies only 10% of the time or lower?
 - c. [10] How do the answers to parts (a) and (b) change if we have 2000 servers?
 - d. [Discussion] Section 6.4 (page 452) discusses “tail-tolerant” designs. What kind of design optimizations would you need to make in your web service (*Hint*: Look at the “Tail at Scale” paper from Dean and Barroso [2013]).

Domain-Specific Architectures

Moore's Law can't continue forever ... We have another 10 to 20 years before we reach a fundamental limit

Gordon Moore,
Intel Co-Founder (2005)

7.1

Introduction

Gordon Moore not only predicted the amazing growth of transistors per chip in 1965, but the opening chapter quote shows that he also predicted its demise 50 years later. As evidence, [Figure 7.1](#) shows that even the company he founded—which for decades proudly used Moore’s Law as a guideline for capital investment—is slowing its development of new semiconductor processes.

During the semiconductor boom time, architects rode Moore’s Law to create novel mechanisms that could turn the cornucopia of transistors into higher performance. The resources for a five-stage pipeline, 32-bit RISC processor—which needed as little as 25,000 transistors in the 1980s—grew by a factor of 100,000 to enable features that accelerated general-purpose code on general-purpose processors, as earlier chapters document:

- 1st-level, 2nd-level, 3rd-level, and even 4th-level caches
- 512-bit SIMD floating-point units
- 15+ stage pipelines
- Branch prediction
- Out-of-order execution
- Speculative prefetching
- Multithreading
- Multiprocessing

These sophisticated architectures targeted million-line programs written in efficient languages like C++. Architects treated such code as black boxes, generally

Figure 7.1 Time before new Intel semiconductor process technology measured in nm. The y-axis is log scale. Note that the time stretched previously from about 24 months per new process step to about 30 months since 2010.

without understanding either the internal structure of the programs or even what they were trying to do. Benchmark programs like those in SPEC2017 were just artifacts to measure and accelerate. Compiler writers were the people at the hardware-software interface, which dates back to the RISC revolution in the 1980s, but they have limited understanding of the high-level application behavior; that's why compilers cannot even bridge the semantic gap between C or C++ and the architecture of GPUs.

As [Chapter 1](#) described, Dennard scaling ended much earlier than Moore's Law. Thus more transistors switching now means more power. The energy budget is not increasing, and we've already replaced the single inefficient processor with multiple efficient cores. Hence, we have nothing left up our sleeves to continue major improvements in cost-performance and energy efficiency for general-purpose architectures. Because the energy budget is limited (because of electromigration, mechanical and thermal limits of chips), if we want higher performance (higher operations/second), we need to lower the energy per operation.

[Figure 7.2](#) is another take on the relative energy costs of memory and logic mentioned in [Chapter 1](#), this time calculated as overhead for an arithmetic instruction. Given this overhead, minor twists to existing cores may get us 10% improvements, but if we want order-of-magnitude improvements while offering programmability, we need to increase the number of arithmetic operations per instruction from one to hundreds. To achieve that level of efficiency, we need a drastic change in computer architecture from general-purpose cores to *domain-specific architectures* (DSAs).

Thus, just as the field switched from uniprocessors to multiprocessors in the past decade out of necessity, desperation is the reason architects are now working on DSAs. The new normal is that a computer will consist of standard processors to run conventional large programs such as operating systems along with domain-specific processors that do only a narrow range of tasks, but they do them extremely well. Thus such computers will be much more heterogeneous than the homogeneous multicore chips of the past.

RISC instruction		Overhead	ALU	125 pJ
Load/Store	D-\$	Overhead	ALU	150 pJ
SP floating point			+	15–20 pJ
32-bit addition			+	7 pJ
8-bit addition			+	0.2–0.5 pJ

Figure 7.2 Energy costs in picoJoules for a 90 nm process to fetch instructions or access a data cache compared to the energy cost of arithmetic operations ([Qadeer et al., 2015](#)).

Part of the argument is that the preceding architecture innovations from the past few decades that leveraged Moore’s Law (caches, out-of-order execution, etc.) may not be a good match to some domains—especially in terms of energy usage—so their resources can be recycled to make the chip a better match to the domain. For example, caches are excellent for general-purpose architectures, but not necessarily for DSAs; for applications with easily predictable memory access patterns or huge data sets like video that have little data reuse, multilevel caches are overkill, hording area and energy that could be put to better use. Therefore the promise of DSAs is both improved silicon efficiency and better energy efficiency, with the latter typically being the more important attribute today.

Architects probably won’t create a DSA for a large C++ program like a compiler as found in the SPEC2017 benchmark. Domain-specific algorithms are almost always for small compute-intensive kernels of larger systems, such as for object recognition or speech understanding. DSAs should focus on the subset and not plan to run the entire program. In addition, changing the code of the benchmark is no longer breaking the rules; it is a perfectly valid source of speedup for DSAs. Consequently, if they are going to make useful contributions, architects interested in DSA must now shed their blinders and learn application domains and algorithms.

In addition to needing to expand their areas of expertise, a challenge for domain-specific architects is to find a target whose demand is large enough to justify allocating dedicated silicon on an SOC or even a custom chip. The *nonrecurring engineering (NRE)* costs of a custom chip and supporting software are amortized over the number of chips manufactured, so it is unlikely to make economic sense if you need only 1000 chips.

One way to accommodate smaller volume applications is to use reconfigurable chips such as FPGAs because they have lower NRE than custom chips *and* because several different applications may be able to reuse the same reconfigurable hardware to amortize its costs (see [Section 7.5](#)). However, since the hardware is less efficient than custom chips, the gains from FPGAs are more modest.

Another DSA challenge is how to port software to it. Familiar programming environments like the C++ programming language and compiler are rarely the right vehicles for a DSA.

The rest of this chapter provides five guidelines for the design of DSAs and then a tutorial on our example domain, which is *deep neural networks (DNNs)*. We chose DNNs because they are revolutionizing many areas of computing today. Unlike some hardware targets, DNNs are applicable to a wide range of problems, so we can reuse a DNN-specific architecture for solutions in speech, vision, language, translation, search ranking, and many more areas.

We follow with four examples of DSAs: two custom chips for the data center that accelerate DNNs, an FPGA for the data center that accelerates many domains, and an image-processing unit designed for *personal mobile devices (PMDs)*. We then compare the cost-performance of the DSAs along with CPUs and GPUs using DNN benchmarks, and conclude with a prediction of an upcoming renaissance for computer architecture.

7.2

Guidelines for DSAs

Here are five principles that generally guided the designs of the four DSAs we'll see in [Sections 7.4–7.7](#). Not only do these five guidelines lead to increased area and energy efficiency, they also provide two valuable bonus effects. First, they lead to simpler designs, which reduce the cost of NRE of DSAs (see the fallacy in [Section 7.10](#)). Second, for user-facing applications that are commonplace with DSAs, accelerators that follow these principles are a better match to the 99th-percentile response-time deadlines than the time-varying performance optimizations of traditional processors, as we will see in [Section 7.9](#). [Figure 7.3](#) shows how the four DSAs followed these guidelines.

1. *Use dedicated memories to minimize the distance over which data is moved.*

The many levels of caches in general-purpose microprocessors use a great deal of area and energy trying to move data optimally for a program. For example, a two-way set associative cache uses 2.5 times as much energy as an equivalent software-controlled scratchpad memory. By definition, the compiler writers and programmers of DSAs understand their domain, so there is no need for the hardware to try to move data for them. Instead, data movement is reduced with software-controlled memories that are dedicated to and tailored for specific functions within the domain.

2. *Invest the resources saved from dropping advanced microarchitectural optimizations into more arithmetic units or bigger memories.*

As [Section 7.1](#) describes, architects turned the bounty from Moore's Law into the resource-intensive optimizations for CPUs and GPUs (out-of-order execution, multithreading, multiprocessing, prefetching, address coalescing, etc.).

Guideline	TPU	Catapult	Crest	Pixel Visual Core
Design target	Data center ASIC	Data center FPGA	Data center ASIC	PMD ASIC/SOC IP
1. Dedicated memories	24 MiB Unified Buffer, 4 MiB Accumulators	Varies	N.A.	Per core: 128 KiB line buffer, 64 KiB P.E. memory
2. Larger arithmetic unit	65,536 Multiply-accumulators	Varies	N.A.	Per core: 256 Multiply-accumulators (512 ALUs)
3. Easy parallelism	Single-threaded, SIMD, in-order	SIMD, MISD	N.A.	MPMD, SIMD, VLIW
4. Smaller data size	8-Bit, 16-bit integer	8-Bit, 16-bit integer 32-bit Fl. Pt.	21-bit Fl. Pt.	8-bit, 16-bit, 32-bit integer
5. Domain-specific lang.	TensorFlow	Verilog	TensorFlow	Halide/TensorFlow

Figure 7.3 The four DSAs in this chapter and how closely they followed the five guidelines. Pixel Visual Core typically has 2–16 cores. The first implementation of Pixel Visual Core does not support 8-bit arithmetic.

Given the superior understanding of the execution of programs in these narrower domains, these resources are much better spent on more processing units or larger on-chip memory.

3. *Use the easiest form of parallelism that matches the domain.*

Target domains for DSAs almost always have inherent parallelism. The key decisions for a DSA are how to take advantage of that parallelism and how to expose it to the software. Design the DSA around the natural granularity of the parallelism of the domain and expose that parallelism simply in the programming model. For example, with respect to data-level parallelism, if SIMD works in the domain, it's certainly easier for the programmer and the compiler writer than MIMD. Similarly, if VLIW can express the instruction-level parallelism for the domain, the design can be smaller and more energy-efficient than out-of-order execution.

4. *Reduce data size and type to the simplest needed for the domain.*

As we will see, applications in many domains are typically memory-bound, so you can increase the effective memory bandwidth and on-chip memory utilization by using narrower data types. Narrower and simpler data also let's you pack more arithmetic units into the same chip area.

5. *Use a domain-specific programming language to port code to the DSA.*

As [Section 7.1](#) mentions, a classic challenge for DSAs is getting applications to run on your novel architecture. A long-standing fallacy is assuming that your new computer is so attractive that programmers will rewrite their code just for your hardware. Fortunately, domain-specific programming languages were becoming popular even before architects were forced to switch their attention to DSAs. Examples are Halide for vision processing and TensorFlow for DNNs ([Ragan-Kelley et al., 2013](#); [Abadi et al., 2016](#)). Such languages make porting applications to your DSA much more feasible. As previously mentioned, only a small, compute-intensive portion of the application needs to run on the DSA in some domains, which also simplifies porting.

DSAs introduce many new terms, mostly from the new domains but also from novel architecture mechanisms not seen in conventional processors. As we did in [Chapter 4](#), [Figure 7.4](#) lists the new acronyms, terms, and short explanations to aid the reader.

7.3

Example Domain: Deep Neural Networks

Artificial intelligence (AI) is not only the next big wave in computing—it's the next major turning point in human history... the Intelligence Revolution will be driven by data, neural networks and computing power. Intel is committed to AI [thus]... we've added a set of leading-edge accelerants required for the growth and widespread adoption of AI.

Brian Krzanich,
Intel CEO (2016)

Area	Term	Acronym	Short explanation
General	Domain-specific architectures	DSA	A special-purpose processor designed for a particular domain. It relies on other processors to handle processing outside that domain
	Intellectual property block	IP	A portable design block that can be integrated into an SOC. They enable a marketplace where organizations offer IP blocks to others who compose them into SOC's
	System on a chip	SOC	A chip that integrates all the components of a computer; commonly found in PMDs
Deep neural networks	Activation	—	Result of “activating” the artificial neuron; the output of the nonlinear functions
	Batch	—	A collection of datasets processed together to lower the cost of fetching weights
	Convolutional neural network	CNN	A DNN that takes as inputs a set of nonlinear functions of spatially nearby regions of outputs from the prior layer, which are multiplied by the weights
	Deep neural network	DNN	A sequence of layers that are collections of artificial neurons, which consist of a nonlinear function applied to products of weights times the outputs of the prior layer
	Inference	—	The production phase of DNNs; also called <i>prediction</i>
	Long short-term memory	LSTM	An RNN well suited to classify, process, and predict time series. It is a hierarchical design consisting of modules called <i>cells</i>
	MultiLayer perceptron	MLP	A DNN that takes as inputs a set of nonlinear functions of all outputs from the prior layer multiplied by the weights. These layers are called <i>fully connected</i>
	Rectified linear unit	<i>ReLU</i>	A nonlinear function that performs $f(x) = \max(x, 0)$. Other popular nonlinear functions are sigmoid and hyperbolic tangent (<i>tanh</i>)
	Recurrent neural network	RNN	A DNN whose inputs are from the prior layer <i>and</i> the previous state
	Training	—	The development phase of DNNs; also called <i>learning</i>
	Weights	—	The values learned during training that are applied to inputs; also called <i>parameters</i>
TPU	Accumulators	—	The 4096 256×32 -bit registers (4 MiB) that collect the output of the MMU and are input to the Activation Unit
	Activation unit	—	Performs the nonlinear functions (ReLU, sigmoid, hyperbolic tangent, max pool, and average pool). Its input comes from the Accumulators and its output goes to the Unified Buffer
	Matrix multiply unit	MMU	A systolic array of 256×256 8-bit arithmetic units that perform multiply-add. Its inputs are the Weight Memory and the Unified Buffer, and its output is the Accumulators
	Systolic array	—	An array of processing units that in lockstep input data from upstream neighbors, compute partial results, and pass some inputs and results to downstream neighbors
	Unified buffer	UB	A 24 MiB on-chip memory that holds the activations. It was sized to try to avoid spilling activations to DRAM when running a DNN
	Weight memory	—	An 8 MiB external DRAM chip containing the weights for the MMU. Weights are transferred to a <i>Weight FIFO</i> before entering the MMU

Figure 7.4 A handy guide to DSA terms used in [Sections 7.3–7.6](#). [Figure 7.29](#) on page 472 has a guide for [Section 7.7](#).

Artificial intelligence (AI) has made a dramatic comeback since the turn of the century. Instead of *building* artificial intelligence as a large set of logical rules, the focus switched to *machine learning* from example data as the path to artificial intelligence. The amount of data needed to learn was much greater than thought. The warehouse scale computers (WSCs) of this century, which harvest and store petabytes of information found on the Internet from the billions of users and their smartphones, supply the ample data. We also underestimated the amount of computation needed to learn from the massive data, but GPUs—which have excellent single-precision floating-point cost-performance—embedded in the thousands of servers of WSCs deliver sufficient computing.

One part of machine learning, called DNNs, has been the AI star for the past five years. Example DNN breakthroughs are in language translation, which DNNs improved more in a single leap than all the advances from the prior decade (Tung, 2016; Lewis-Kraus, 2016); the switch to DNNs in the past five years reduced the error rate in an image recognition competition from 26% to 3.5% (Krizhevsky et al., 2012; Szegedy et al., 2015; He et al., 2016); and in 2016, DNNs enabled a computer program for the first time to beat a human champion at Go (Silver et al., 2016). Although many of these run in the cloud, they have also enabled Google Translate on smartphones, which we described in Chapter 1. In 2017 new, significant DNN results appear nearly every week.

Readers interested in learning more about DNNs than found in this section should download and try the tutorials in TensorFlow (TensorFlow Tutorials, 2016), or for the less adventurous, consult a free online textbook on DNNs (Nielsen, 2016).

The Neurons of DNNs

DNNs were inspired by the neuron of the brain. The artificial neuron used for neural networks simply computes the sum over a set of products of *weights* or *parameters* and data values that is then put through a nonlinear function to determine its output. As we will see, each artificial neuron has a large fan-in and a large fan-out.

For an image-processing DNN, the input data would be the pixels of a photo, with the pixel values multiplied by the weights. Although many nonlinear functions have been tried, a popular one today is simply $f(x) = \max(x, 0)$, which returns 0 if the x is negative or the original value if positive or zero. (This simple function goes by the complicated name *rectified linear unit* or *ReLU*.) The output of a nonlinear function is called an *activation*, in that it is the output of the artificial neuron that has been “activated.”

A cluster of artificial neurons might process different portions of the input, and the output of that cluster becomes the input to the next layer of artificial neurons. The layers between the input layer and the output layer are called *hidden layers*. For image processing, you can think of each layer as looking for different types of features, going from lower-level ones like edges and angles to higher-level ones like eyes and ears. If the image-processing application was trying to decide if the image

Name	DNN layers	Weights	Operations/Weight
MLP0	5	20M	200
MLP1	4	5M	168
LSTM0	58	52M	64
LSTM1	56	34M	96
CNN0	16	8M	2888
CNN1	89	100M	1750

Figure 7.5 Six DNN applications that represent 95% of DNN workloads for inference at Google in 2016, which we use in [Section 7.9](#). The columns are the DNN name, the number of layers in the DNN, the number of weights, and operations per weight (operational intensity). [Figure 7.41](#) on page 595 goes into more detail on these DNNs.

contained a dog, the output of the last layer could be a probability number between 0 and 1 or perhaps a list of probabilities corresponding to a list of dog breeds.

The number of layers gave DNNs their name. The original lack of data and computing horsepower kept most neural networks relatively shallow. [Figure 7.5](#) shows the number of layers for a variety of recent DNNs, the number of weights, and the number of operations per weight fetched. In 2017 some DNNs have 150 layers.

Training Versus Inference

The preceding discussion concerns DNNs that are in production. DNN development starts by defining the neural network architecture, picking the number and type of layers, the dimensions of each layer, and the size of the data. Although experts may develop new neural network architectures, most practitioners will choose among the many existing designs (e.g., [Figure 7.5](#)) that have been shown to perform well on problems similar to theirs.

Once the neural architecture has been selected, the next step is to learn the weights associated with each edge in the neural network graph. The weights determine the behavior of the model. Depending on the choice of neural architecture, there can be anywhere from thousands to hundreds of millions of weights in a single model (see [Figure 7.5](#)). Training is the costly process of tuning these weights so that the DNN approximates the complex function (e.g., mapping from pictures to the objects in that picture) described by the training data.

This development phase is universally called *training* or *learning*, whereas the production phase has many names: *inference*, *prediction*, *scoring*, *implementation*, *evaluation*, *running*, or *testing*. Most DNNs use *supervised learning* in that they are given a training set to learn from where the data is preprocessed in order to have the correct labels. Thus, in the ImageNet DNN competition ([Russakovsky et al., 2015](#)), the training set consists of 1.2 million photos, and each photo has been labeled as one of 1000 categories. Several of these categories

are quite detailed, such as specific breeds of dogs and cats. The winner is determined by evaluating a separate secret set of 50,000 photos to see which DNN has the lowest error rate.

Setting the weights is an iterative process that goes *backward* through the neural network using the training set. This process is called *backpropagation*. For example, because you know the breed of a dog image in the training set, you see what your DNN says about the image, and then you adjust the weights to improve the answer. Amazingly, the weights at the start of the training process should be set to random data, and you just keep iterating until you're satisfied with the DNN accuracy using the training set.

For the mathematically inclined, the goal of learning is to find a function that maps the inputs to the correct outputs over the multilayer neural network architecture. Backpropagation stands for “back propagation of errors.” It calculates a gradient over all the weights as input to an optimization algorithm that tries to minimize the errors by updating the weights. The most popular optimization algorithm for DNNs is *stochastic gradient descent*. It adjusts the weights proportionally to maximize the descent of the gradient obtained from backpropagation. Readers interested in learning more should see [Nielsen \(2016\)](#) or [TensorFlow Tutorials \(2016\)](#).

Training can take weeks of computation, as [Figure 7.6](#) shows. The inference phase is often below 100 ms per data sample, which is a million times less. Although training takes much longer than a single inference, the total compute time for inference is a product of the number of customers of the DNN and how frequently they invoke it.

After training, you deploy your DNN, hoping that your training set is representative of the real world, and that your DNN will be so popular that your users will spend much more time employing it than you've put into developing it!

Type of data	Problem area	Size of benchmark's training set	DNN architecture	Hardware	Training time
text [1]	Word prediction (word2vec)	100 billion words (Wikipedia)	2-layer skip gram	1 NVIDIA Titan X GPU	6.2 hours
audio [2]	Speech recognition	2000 hours (Fisher Corpus)	11-layer RNN	1 NVIDIA K1200 GPU	3.5 days
images [3]	Image classification	1 million images (ImageNet)	22-layer CNN	1 NVIDIA K20 GPU	3 weeks
video [4]	activity recognition	1 million videos (Sports-1M)	8-layer CNN	10 NVIDIA GPUs	1 month

Figure 7.6 Training set sizes and training time for several DNNs ([Iandola, 2016](#)).

There are tasks that don't have training datasets, such as when trying to predict the future of some real-world event. Although we won't cover it here, *reinforcement learning (RL)* is a popular algorithm for such learning in 2017. Instead of a training set to learn from, RL acts on the real world and then gets a signal from a reward function, depending on whether that action made the situation better or worse.

Although it's hard to imagine a faster changing field, only three types of DNNs reign as most popular in 2017: *MultiLayer Perceptrons (MLPs)*, *Convolutional Neural Networks (CNNs)*, and *Recurrent Neural Networks (RNNs)*. They are all examples of supervised learning, which rely on training sets.

Multilayer Perceptron

MLPs were the original DNNs. Each new layer is a set of nonlinear functions F of weighted sum of all outputs from a prior one $y_n = F(W \times y_{n-1})$. The weighted sum consists of a vector-matrix multiply of the outputs with the weights (see [Figure 7.7](#)). Such a layer is called *fully connected* because each output neuron result depends on *all* input neurons of the prior layer.

We can calculate the number of neurons, operations, and weights per layer for each of the DNN types. The easiest is MLP because it is just a vector-matrix

Figure 7.7 MLP showing the input **Layer[i-1]** on the left and the output **Layer[i]** on the right. ReLU is a popular nonlinear function for MLPs. The dimensions of the input and output layers are often different. Such a layer is called *fully connected* because it depends on all the inputs from the prior layer, even if many of them are zeros. One study suggested that 44% were zeros, which presumably is in part because ReLU turns negative numbers into zeros.

multiply of the input vector times the weights array. Here are the parameters and the equations to determine weights and operations for inference (we count multiply and add as two operations):

- $\text{Dim}[i]$: Dimension of the output vector, which is the number of neurons
- $\text{Dim}[i-1]$: Dimension of the input vector
- Number of weights: $\text{Dim}[i-1] \times \text{Dim}[i]$
- Operations: $2 \times \text{Number of weights}$
- Operations/Weight: 2

This final term is the *operational intensity* from the Roofline model discussed in [Chapter 4](#). We use operations per *weight* because there can be millions of weights, which usually don't fit on the chip. For example, the dimensions of one stage of an MLP in [Section 7.9](#) has $\text{Dim}[i-1]=4096$ and $\text{Dim}[i]=2048$, so for that layer, the number of neurons is 2048, number of weights is 8,388,608, the number of operations is 16,777,216, and the operational intensity is 2. As we recall from the Roofline model, low operational intensity makes it harder to deliver high performance.

Convolutional Neural Network

CNNs are widely used for computer vision applications. As images have a two-dimensional structure, neighboring pixels are the natural place to look to find relationships. CNNs take as inputs a set of nonlinear functions from spatially nearby regions of outputs from the prior layer and then multiplies by the weights, which reuses the weights many times.

The idea behind CNNs is that each layer raises the level of abstraction of the image. For example, the first layer might identify only horizontal lines and vertical lines. The second layer might combine them to identify corners. The next step might be rectangles and circles. The following layer could use that input to detect portions of a dog, like eyes or ears. The higher layers would be trying to identify characteristics of different breeds of dogs.

Each neural layer produces a set of two-dimensional *feature maps*, where each cell of the two-dimensional feature map is trying to identify one feature in the corresponding area of the input.

[Figure 7.8](#) shows the starting point where a 2×2 stencil computation from the input image creates the elements of the first feature map. A *stencil computation* uses neighboring cells in a fixed pattern to update all the elements of an array. The number of output feature maps will depend on how many different features you are trying to capture from the image and the stride used to apply the stencil.

The process is actually more complicated because the image is usually not just a single, flat two-dimensional layer. Typically, a color image will have three levels for red, green, and blue. For example, a 2×2 stencil will access 12 elements: 2×2

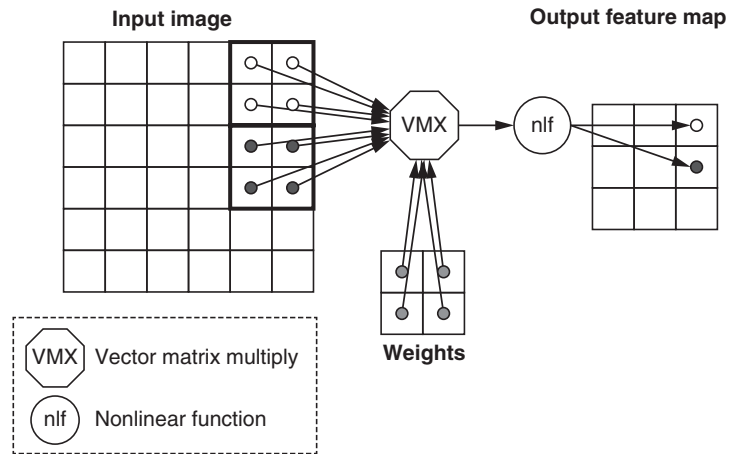

Figure 7.8 Simplified first step of a CNN. In this example, every group of four pixels of the input image are multiplied by the same four weights to create the cells of the output feature map. The pattern depicted shows a stride of two between the groups of input pixels, but other strides are possible. To relate this figure to MLP, you can think of each 2×2 convolution as a tiny fully connected operation to produce one point of the output feature map. Figure 7.9 shows how multiple feature maps turn the points into a vector in the third dimension.

of red pixels, 2×2 of green pixels, and 2×2 of blue pixels. In this case, you need 12 weights per output feature map for a 2×2 stencil on three input levels of an image.

Figure 7.9 shows the general case of an arbitrary number of input and output feature maps, which occurs after that first layer. The calculation is a three-dimensional stencil over all the input feature maps with a set of weights to produce one output feature map.

For the mathematically oriented, if the number of input feature maps and output feature maps both equal 1 and the stride is 1, then a single layer of a two-dimensional CNN is the same calculation as a two-dimensional discrete convolution.

As we see in Figure 7.9, CNNs are more complicated than MLPs. Here are the parameter and the equations to calculate the weights and operations:

- $\text{DimFM}[i-1]$: Dimension of the (square) input Feature Map
- $\text{DimFM}[i]$: Dimension of the (square) output Feature Map
- $\text{DimSten}[i]$: Dimension of the (square) stencil
- $\text{NumFM}[i-1]$: Number of input Feature Maps
- $\text{NumFM}[i]$: Number of output Feature Maps
- Number of neurons: $\text{NumFM}[i] \times \text{DimFM}[i]^2$

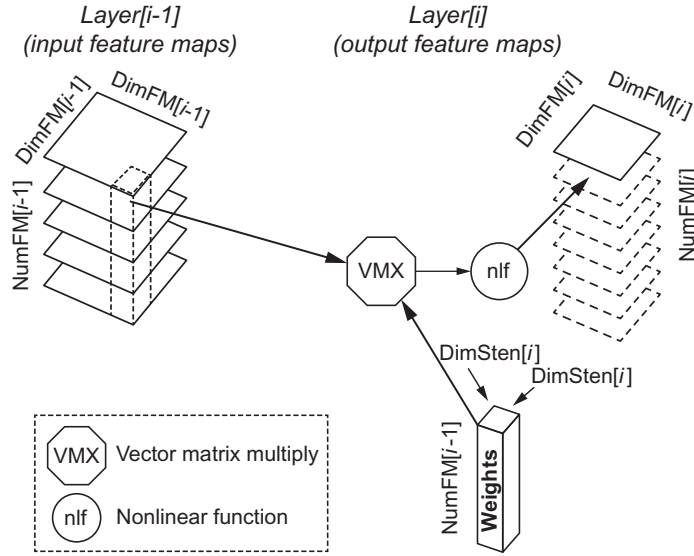

Figure 7.9 CNN general step showing input feature maps of Layer[i-1] on the left, the output feature maps of Layer[i] on the right, and a three-dimensional stencil over input feature maps to produce a single output feature map. Each output feature map has its own unique set of weights, and the vector-matrix multiply happens for every one. The dotted lines show future output feature maps in this figure. As this figure illustrates, the dimensions and number of the input and output feature maps are often different. As with MLPs, ReLU is a popular nonlinear function for CNNs.

- Number of weights per output Feature Map: $\text{NumFM}[i-1] \times \text{DimSten}[i]^2$
- Total number of weights per layer: $\text{NumFM}[i] \times \text{Number of weights per output Feature Map}$
- Number of operations per output Feature Map: $2 \times \text{DimFM}[i]^2 \times \text{Number of weights per output Feature Map}$
- Total number of operations per layer: $\text{NumFM}[i] \times \text{Number of operations per output Feature Map} = 2 \times \text{DimFM}[i]^2 \times \text{NumFM}[i] \times \text{Number of weights per output Feature Map} = 2 \times \text{DimFM}[i]^2 \times \text{Total number of weights per layer}$
- Operations/Weight: $2 \times \text{DimFM}[i]^2$

A CNN in [Section 7.9](#) has a layer with $\text{DimFM}[i-1] = 28$, $\text{DimFM}[i] = 14$, $\text{DimSten}[i] = 3$, $\text{NumFM}[i-1] = 64$ (number of input feature maps), and $\text{NumFM}[i] = 128$ (number of output feature maps). That layer has 25,088 neurons, 73,728 weights, does 28,901,376 operations, and has an operational intensity of 392. As our example indicates, CNN layers generally have fewer weights and greater operational intensity than the fully connected layers found in MLPs.

Recurrent Neural Network

The third type of DNN is RNNs, which are popular for speech recognition or language translation. RNNs add the ability to explicitly model sequential inputs by adding state to the DNN model so that RNNs can remember facts. It's analogous to the difference in hardware between combinational logic and a state machine. For example, you might learn the gender of the person, which you would want to pass along to remember later when translating words. Each layer of an RNN is a collection of weighted sums of inputs from the prior layer and the previous state. The weights are reused across time steps.

Long short-term memory (LSTM) is by far the most popular RNN today. LSTMs mitigate a problem that previous RNNs had with their inability to remember important long-term information.

Unlike the other two DNNs, LSTM is a hierarchical design. LSTM consists of modules called *cells*. You can think of cells as templates or macros that are linked together to create the full DNN model, similar to how layers of an MLP line up to form a complete DNN model.

Figure 7.10 shows how the LSTM cells are linked together. They are hooked up from left to right, connecting the output of one cell to the input of the next. They are also unrolled in time, which runs top down in Figure 7.10. Thus a sentence is input a word at a time per iteration of the unrolled loop. The long-term and short-term memory information that gives the LSTM its name is also passed top-down from one iteration to the next.

Figure 7.11 shows the contents of an LSTM cell. As we would expect from Figure 7.10, the input is on the left, the output is on the right, the two memory inputs are at the top, and the two memory outputs are at the bottom.

Each cell does five vector-matrix multiplies using five unique sets of weights. The matrix multiply on the input is just like the MLP in Figure 7.7. Three others are called *gates* in that they gate or limit how much information from one source is passed along to the standard output or the memory output. The amount of information sent per gate is set by their weights. If the weights are mostly zeros or small values, then little gets through; conversely, if they are mostly large, then the gate lets most information flow. The three gates are called the *input gate*, the *output gate*, and the *forget gate*. The first two filter the input and output, and the last one determines what to forget along the long-term memory path.

The short-term memory output is a vector-matrix multiply using the Short Term Weights and the output of this cell. The short-term label is applied because it does not directly use any of the inputs to the cell.

Because the LSTM cell inputs and outputs are all connected together, the size of the three input-output pairs must be the same. Looking inside the cell, there are enough dependencies that all of the inputs and outputs are often the same size. Let's assume they are all the same size, called *Dim*.

Even so, the vector-matrix multiplies are not all the same size. The vectors for the three gate multiplies are $3 \times \text{Dim}$, because the LSTM concatenates all three inputs. The vector for the input multiply is $2 \times \text{Dim}$, because the LSTM

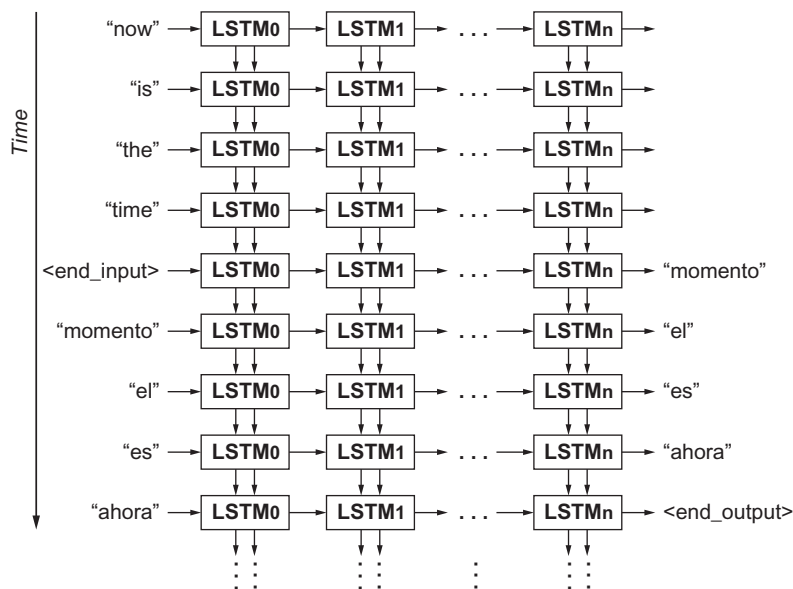

Figure 7.10 LSTM cells connected together. The inputs are on the left (English words), and the outputs are on the right (the translated Spanish words). The cells can be thought of as being unrolled over time, from top to bottom. Thus the short-term and long-term memory of LSTM is implemented by passing information top-down between unrolled cells. They are unrolled enough to translate whole sentences or even paragraphs. Such sequence-to-sequence translation models delay their output until they get to the end of the input (Wu et al., 2016). They produce the translation in *reverse order*, using the most recent translated word as input to the next step, so “now is the time” becomes “ahora es el momento.” (This figure and the next are often shown turned 90 degrees in LSTM literature, but we’ve rotated them to be consistent with Figures 7.7 and 7.8.)

concatenates the input with the short-term memory input as the vector. The vector for the last multiply is just $1 \times \text{Dim}$, because it is just the output.

Now we can finally calculate the weights and operations:

- Number of weights per cell: $3 \times (3 \times \text{Dim} \times \text{Dim}) + (2 \times \text{Dim} \times \text{Dim}) + (1 \times \text{Dim} \times \text{Dim}) = 12 \times \text{Dim}^2$
- Number of operations for the 5 vector-matrix multiplies per cell: $2 \times \text{Number of weights per cell} = 24 \times \text{Dim}^2$
- Number of operations for the 3 element-wise multiplies and 1 addition (vectors are all the size of the output): $4 \times \text{Dim}$
- Total number of operations per cell (5 vector-matrix multiplies and the 4 element-wise operations): $24 \times \text{Dim}^2 + 4 \times \text{Dim}$
- Operations/Weight: ~ 2

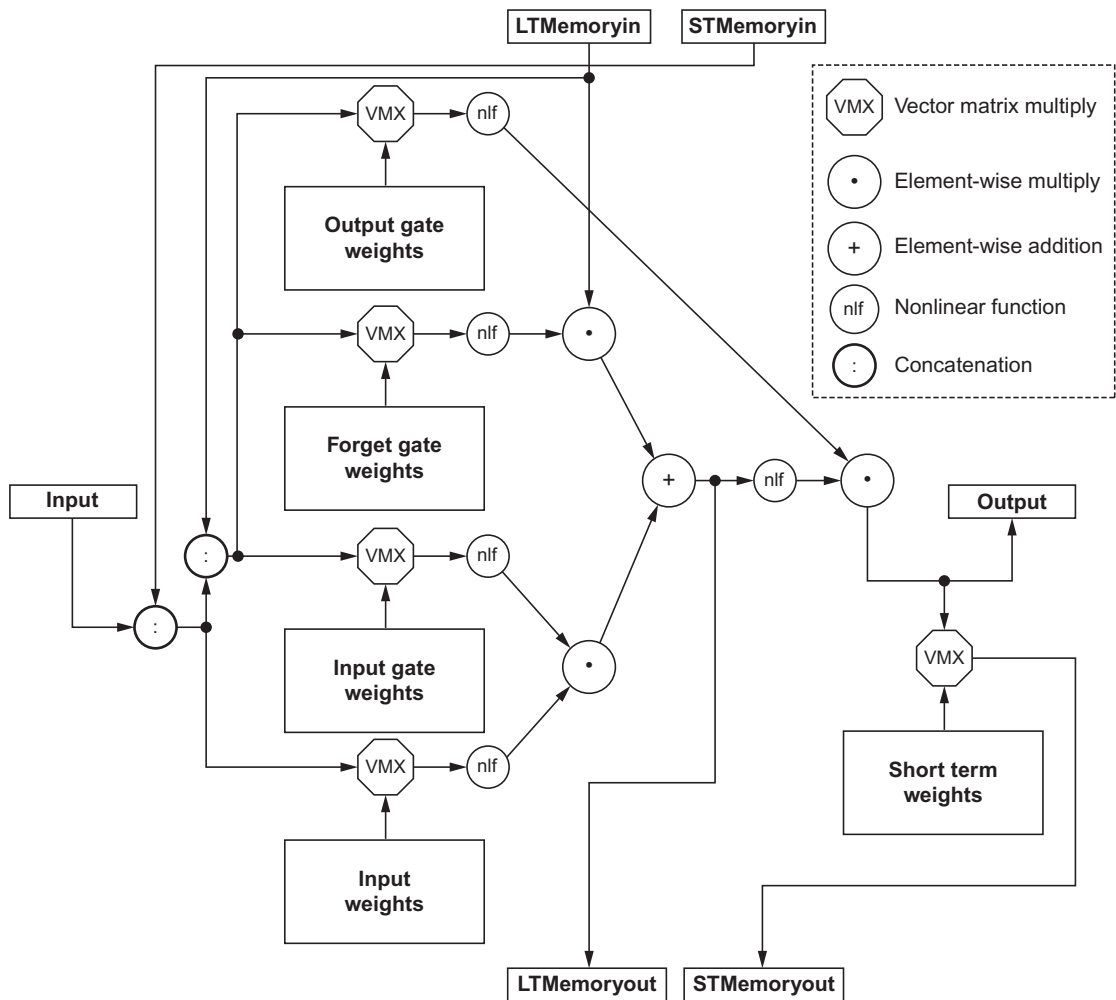

Figure 7.11 This LSTM cell contains 5 vector-matrix multiplies, 3 element-wise multiplies, 1 element-wise add, and 6 nonlinear functions. The standard input and short-term memory input are concatenated to form the vector operand for the input vector-matrix multiply. The standard input, long-term memory input, and short-term memory input are concatenated to form the vector that is used in three of the other four vector-matrix multiplies. The nonlinear functions for the three gates are Sigmoids $f(x) = 1/(1 + \exp(-x))$; the others are hyperbolic tangents. (This figure and the previous one are often shown turned 90 degrees in LSTM literature, but we’ve rotated them to be consistent with Figures 7.7 and 7.8.)

Dim is 1024 for one of the six cells of an LSTM in Section 7.9. Its number of weights is 12,582,912, its number of operations is 25,169,920, and its operational intensity is 2.0003. Thus LSTMs are like MLPs in that they typically have more weights and a lower operational intensity than CNNs.

Batches

Because DNNs can have many weights, a performance optimization is to reuse the weights once they have been fetched from memory across a set of inputs, thereby increasing effective operational intensity. For example, an image-processing DNN might work on a set of 32 images at a time to reduce the effective cost of fetching weights by a factor of 32. Such datasets are called *batches* or *minibatches*. In addition to improving the performance of inference, backpropagation needs a batch of examples instead of one at a time in order to train well.

Looking at an MLP in [Figure 7.7](#), a batch can be seen as a sequence of input row vectors, which you can think of as a matrix with a height dimension that matches the batch size. A sequence of row vector inputs to the five matrix multiplies of LSTMs in [Figure 7.11](#) can also be considered a matrix. In both cases, computing them as matrices instead of sequentially as independent vectors improves computing efficiency.

Quantization

Numerical precision is less important for DNNs than for many applications. For example, there is no need for double-precision floating-point arithmetic, which is the standard bearer of high-performance computing. It's even unclear that you need the full accuracy of the IEEE 754 floating-point standard, which aims to be accurate within one-half of a unit in the last place of the floating-point significand.

To take advantage of the flexibility in numerical precision, some developers use fixed point instead of floating point for the inference phase. (Training is almost always done in floating-point arithmetic.) This conversion is called *quantization*, and such a transformed application is said to be *quantized* ([Vanhoucke et al., 2011](#)). The fixed-point data width is usually 8 or 16 bits, with the standard multiply-add operation accumulating at twice the width of the multiplies. This transformation typically occurs after training, and it can reduce DNN accuracy by a few percentage points ([Bhattacharya and Lane, 2016](#)).

Summary of DNNs

Even this quick overview suggests that DSAs for DNNs will need to perform at least these matrix-oriented operations well: vector-matrix multiply, matrix-matrix multiply, and stencil computations. They will also need support for the nonlinear functions, which include at a minimum ReLU, Sigmoid, and tanh. These modest requirements still leave open a very large design space, which the next four sections explore.

7.4

Google's Tensor Processing Unit, an Inference Data Center Accelerator

The Tensor Processing Unit (TPU)¹ is Google's first custom ASIC DSA for WSCs. Its domain is the inference phase of DNNs, and it is programmed using the TensorFlow framework, which was designed for DNNs. The first TPU was been deployed in Google data centers in 2015.

The heart of the TPU is a 65,536 (256×256) 8-bit ALU Matrix Multiply Unit and a large software-managed on-chip memory. The TPU's single-threaded, deterministic execution model is a good match to the 99th-percentile response-time requirement of the typical DNN inference application.

TPU Origin

Starting as far back as 2006, Google engineers had discussions about deploying GPUs, FPGAs, or custom ASICs in their data centers. They concluded that the few applications that could run on special hardware could be done virtually for free using the excess capacity of the large data centers, and it's hard to improve on free. The conversation changed in 2013 when it was projected that if people used voice search for three minutes a day using speech recognition DNNs, it would have required Google's data centers to double in order to meet computation demands. That would be very expensive to satisfy with conventional CPUs. Google then started a high-priority project to quickly produce a custom ASIC for inference (and bought off-the-shelf GPUs for training). The goal was to improve cost-performance by $10\times$ over GPUs. Given this mandate, the TPU was designed, verified (Steinberg, 2015), built, and deployed in data centers in just 15 months.

TPU Architecture

To reduce the chances of delaying deployment, the TPU was designed to be a coprocessor on the PCIe I/O bus, which allows it to be plugged into existing servers. Moreover, to simplify hardware design and debugging, the host server sends instructions over the PCIe bus directly to the TPU for it to execute, rather than having the TPU fetch the instructions. Thus the TPU is closer in spirit to an FPU (floating-point unit) coprocessor than it is to a GPU, which fetches instructions from its memory.

Figure 7.12 shows the block diagram of the TPU. The host CPU sends TPU instructions over the PCIe bus into an instruction buffer. The internal blocks are typically connected together by 256-byte-wide (2048-bits) paths. Starting in the upper-right corner, the *Matrix Multiply Unit* is the heart of the TPU. It contains

¹This section is based on the paper "In-Datacenter Performance Analysis of a Tensor Processing Unit" Jouppi et al., 2017, of which one of your book authors was a coauthor.

Figure 7.12 TPU Block Diagram. The PCIe bus is Gen3 × 16. The main computation part is the light-shaded Matrix Multiply Unit in the upper-right corner. Its inputs are the medium-shaded Weight FIFO and the medium-shaded Unified Buffer and its output is the medium-shaded Accumulators. The light-shaded Activation Unit performs the non-linear functions on the Accumulators, which go to the Unified Buffer.

256 × 256 ALUs that can perform 8-bit multiply-and-adds on signed or unsigned integers. The 16-bit products are collected in the 4 MiB of 32-bit *Accumulators* below the matrix unit. When using a mix of 8-bit weights and 16-bit activations (or vice versa), the Matrix Unit computes at half-speed, and it computes at a quarter-speed when both are 16 bits. It reads and writes 256 values per clock cycle and can perform either a matrix multiply or a convolution. The nonlinear functions are calculated by the *Activation* hardware.

The weights for the matrix unit are staged through an on-chip *Weight FIFO* that reads from an off-chip 8 GiB DRAM called *Weight Memory* (for inference, weights are read-only; 8 GiB supports many simultaneously active models). The intermediate results are held in the 24 MiB on-chip *Unified Buffer*, which can serve as inputs to the Matrix Multiply Unit. A programmable DMA controller transfers data to or from CPU Host memory and the Unified Buffer.

TPU Instruction Set Architecture

As instructions are sent over the relatively slow PCIe bus, TPU instructions follow the CISC tradition, including a repeat field. The TPU does not have a program counter, and it has no branch instructions; instructions are sent from the host CPU. The clock cycles per instruction (CPI) of these CISC instructions are typically 10–20. It has about a dozen instructions overall, but these five are the key ones:

1. `Read_Host_Memory` reads data from the CPU host memory into the Unified Buffer.
2. `Read_Weights` reads weights from Weight Memory into the Weight FIFO as input to the Matrix Unit.
3. `MatrixMultiply/Convolve` causes the Matrix Multiply Unit to perform a matrix-matrix multiply, a vector-matrix multiply, an element-wise matrix multiply, an element-wise vector multiply, or a convolution from the Unified Buffer into the Accumulators. A matrix operation takes a variable-sized $B \times 256$ input, multiplies it by a 256×256 constant input, and produces a $B \times 256$ output, taking B pipelined cycles to complete. For example, if the input were 4 vectors of 256 elements, B would be 4, so it would take 4 clock cycles to complete.
4. `Activate` performs the nonlinear function of the artificial neuron, with options for ReLU, Sigmoid, tanh, and so on. Its inputs are the Accumulators, and its output is the Unified Buffer.
5. `Write_Host_Memory` writes data from the Unified Buffer into the CPU host memory.

The other instructions are alternate host memory read/write, set configuration, two versions of synchronization, interrupt host, debug-tag, nop, and halt. The CISC `MatrixMultiply` instruction is 12 bytes, of which 3 are Unified Buffer address; 2 are accumulator address; 4 are length (sometimes 2 dimensions for convolutions); and the rest are opcode and flags.

The goal is to run whole inference models in the TPU to reduce interactions with the host CPU and to be flexible enough to match the DNN needs of 2015 and beyond, instead of just what was required for 2013 DNNs.

TPU Microarchitecture

The microarchitecture philosophy of the TPU is to keep the Matrix Multiply Unit busy. The plan is to hide the execution of the other instructions by overlapping their execution with the `MatrixMultiply` instruction. Thus each of the preceding four general categories of instructions have separate execution hardware (with read and write host memory combined into the same unit). To increase instruction parallelism further, the `Read_Weights` instruction follows the decoupled access/

execute philosophy (Smith, 1982b) in that they can complete after sending their addresses but before the weights are fetched from Weight Memory. The matrix unit has not-ready signals from the Unified Buffer and the Weight FIFO that will cause the matrix unit to stall if their data are not yet available.

Note that a TPU instruction can execute for many clock cycles, unlike the traditional RISC pipeline with one clock cycle per stage.

Because reading a large SRAM is much more expensive than arithmetic, the Matrix Multiply Unit uses systolic execution to save energy by reducing reads and writes of the Unified Buffer (Kung and Leiserson, 1980; Ramacher et al., 1991; Ovtcharov et al., 2015b). A *systolic array* is a two-dimensional collection of arithmetic units that each independently compute a partial result as a function of inputs from other arithmetic units that are considered upstream to each unit. It relies on data from different directions arriving at cells in an array at regular intervals where they are combined. Because the data flows through the array as an advancing wave front, it is similar to blood being pumped through the human circulatory system by the heart, which is the origin of the systolic name.

Figure 7.13 demonstrates how a systolic array works. The six circles at the bottom are the multiply-accumulate units that are initialized with the weights w_i . The staggered input data x_i are shown coming into the array from above. The 10 steps of the figure represent 10 clock cycles moving down from top to bottom of the page. The systolic array passes the inputs down and the products and sums to the right. The desired sum of products emerges as the data completes its path through the systolic array. Note that in a systolic array, the input data is read only once from memory, and the output data is written only once to memory.

In the TPU, the systolic array is rotated. Figure 7.14 shows that the weights are loaded from the top and the input data flows into the array in from the left. A given 256-element multiply-accumulate operation moves through the matrix as a diagonal wave front. The weights are preloaded and take effect with the advancing wave alongside the first data of a new block. Control and data are pipelined to give the illusion that the 256 inputs are read at once, and after a feed delay, they update one location of each of 256 accumulator memories. From a correctness perspective, software is unaware of the systolic nature of the matrix unit, but for performance, it does worry about the latency of the unit.

TPU Implementation

The TPU chip was fabricated using the 28-nm process. The clock rate is 700 MHz. Figure 7.15 shows the floor plan of the TPU. Although the exact die size is not revealed, it is less than half the size of an Intel Haswell server microprocessor, which is 662 mm².

The 24 MiB Unified Buffer is almost a third of the die, and the Matrix Multiply Unit is a quarter, so the datapath is nearly two-thirds of the die. The 24 MiB size was picked in part to match the pitch of the Matrix Unit on the die and, given the

Figure 7.13 Example of systolic array in action, from top to bottom on the page. In this example, the six weights are already inside the multiply-accumulate units, as is the norm for the TPU. The three inputs are staggered in time to get the desired effect, and in this example are shown coming in from the top. (In the TPU, the data actually comes in from the left.) The array passes the data down to the next element and the result of the computation to the right to the next element. At the end of the process, the sum of products is found to the right. Figure 7.14 Systolic data flow of the Matrix Multiply Unit.

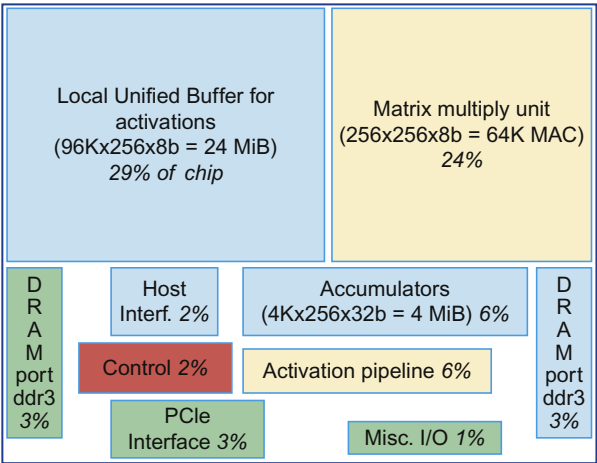

Figure 7.15 Floor plan of TPU die. The shading follows Figure 7.14. The light data buffers are 37%, the light computation units are 30%, the medium I/O is 10%, and the dark control is just 2% of the die. Control is much larger (and much more difficult to design) in a CPU or GPU. The unused white space is a consequence of the emphasis on time to tape-out for the TPU.

Figure 7.16 TPU printed circuit board. It can be inserted into the slot for an SATA disk in a server, but the card uses the PCIe bus.

short development schedule, in part to simplify the compiler. Control is just 2%. [Figure 7.16](#) shows the TPU on its printed circuit card, which inserts into existing servers in a SATA disk slot.

TPU Software

The TPU software stack had to be compatible with that developed for CPUs and GPUs so that applications could be ported quickly. The portion of the application run on the TPU is typically written using TensorFlow and is compiled into an API that can run on GPUs or TPUs ([Larabel, 2016](#)). [Figure 7.17](#) shows TensorFlow code for a portion of an MLP.

Like GPUs, the TPU stack is split into a User Space Driver and a Kernel Driver. The Kernel Driver is lightweight and handles only memory management and interrupts. It is designed for long-term stability. The User Space driver changes frequently. It sets up and controls TPU execution, reformats data into TPU order, and translates API calls into TPU instructions and turns them into an application binary. The User Space driver compiles a model the first time it is evaluated, caching the program image and writing the weight image into the TPU Weight Memory; the second and following evaluations run at full speed. The TPU runs most models completely from inputs to outputs, maximizing the ratio of TPU compute time to I/O time. Computation is often done one layer at a time, with overlapped execution allowing the matrix unit to hide most noncritical path operations.

}

```

Figure 7.17 Portion of the TensorFlow program for the MNIST MLP. It has two hidden 256×256 layers, with each layer using a ReLU as its nonlinear function.

Improving the TPU

The TPU architects looked at variations of the microarchitecture to see whether they could have improved the TPU.

Like an FPU, the TPU coprocessor has a relatively easy microarchitecture to evaluate, so the TPU architects created a performance model and estimated performance as the memory bandwidth, the matrix unit size, and the clock rate and number of accumulators varied. Measurements using TPU hardware counters found that the modeled performance was on average within 8% of the hardware.

Figure 7.18 Performance as metrics scale from $0.25\times$ to $4\times$: memory bandwidth, clock rate+accumulators, clock rate, matrix unit dimension+accumulators, and one dimension of the square matrix unit This is the average performance calculated from six DNN applications in Section 7.9. The CNNs tend to be computation-bound, but the MLPs and LSTMs are memory-bound. Most applications benefit from a faster memory, but a faster clock makes little difference, and a bigger matrix unit actually hurts performance. This performance model is only for code running inside the TPU and does not factor in the CPU host overhead.

Figure 7.18 shows the performance sensitivity of the TPU as these parameters scale over the range for $0.25\times$ to $4\times$. (Section 7.9 lists the benchmarks used.) In addition to evaluating the impact of only raising clock rates (*clock* in Figure 7.18), Figure 7.18 also plots a design (*clock+*) that increases the clock rate and scales the number of accumulators correspondingly so that the compiler can keep more memory references in flight. Likewise, Figure 7.18 plots matrix unit expansion if the number of accumulators increase with the square of the rise in one dimension (*matrix+*), because the matrix grows in both dimensions, as well as only increasing the matrix unit (*matrix*).

First, increasing memory bandwidth (*memory*) has the biggest impact: performance improves $3\times$ on average when memory bandwidth increases $4\times$, because it reduces the time waiting for weight memory. Second, clock rate has little benefit on average with or without more accumulators. Third, the average performance in Figure 7.18 slightly *degrades* when the matrix unit expands from 256×256 to 512×512 for all applications, whether or not they get more accumulators. The issue is analogous to internal fragmentation of large pages, only worse because it's in two dimensions.

Consider the 600×600 matrix used in LSTM1. With a 256×256 matrix unit, it takes nine steps to tile 600×600 , for a total of $18\mu\text{s}$ of time. The larger 512×512 unit requires only four steps, but each step takes four times longer, or $32\mu\text{s}$ of time. The TPU's CISC instructions are long, so decode is insignificant and does not hide the overhead of loading from the DRAM.

Given these insights from the performance model, the TPU architects next evaluated an alternative and hypothetical TPU that they might have designed in the same process technology if they'd had more than 15 months to do so. More aggressive logic synthesis and block design might have increased the clock rate by 50%. The architects found that designing an interface circuit for GDDR5 memory, as used by the K80, would improve Weight Memory bandwidth by more than a factor of five. As [Figure 7.18](#) shows, increasing clock rate to 1050 MHz, but not helping memory, made almost no change in performance. If the clock is left at 700 MHz, but it uses GDDR5 instead for Weight Memory, performance is increased by $3.2\times$, even accounting for the host CPU overhead of invoking the DNN on the revised TPU. Doing both does not improve average performance further.

Summary: How TPU Follows the Guidelines

Despite living on an I/O bus and having relatively little memory bandwidth that limits full utilization of the TPU, a small fraction of a big number can, nonetheless, be relatively large. As we will see in [Section 7.9](#), the TPU delivered on its goal of a tenfold improvement in cost-performance over the GPU when running DNN inference applications. Moreover, a redesigned TPU with the only change being a switch to the same memory technology as in the GPU would be three times faster.

One way to explain the TPU's success is to see how it followed the guidelines in [Section 7.2](#).

1. *Use dedicated memories to minimize the distance over which data is moved.*
The TPU has the 24 MiB Unified Buffer that holds the intermediate matrices and vectors of MLPs and LSTMs and the feature maps of CNNs. It is optimized for accesses of 256 bytes at a time. It also has the 4 MiB Accumulators, each 32-bits wide, that collect the output of the Matrix Unit and act as input to the hardware that calculates the nonlinear functions. The 8-bit weights are stored in a separate off-chip weight memory DRAM and are accessed via an on-chip weight FIFO. In contrast, all these types and sizes of data would exist in redundant copies at several levels of the inclusive memory hierarchy of a general-purpose CPU.
2. *Invest the resources saved from dropping advanced microarchitectural optimizations into more arithmetic units or bigger memories.*
The TPU offers 28 MiB of dedicated memory and 65,536 8-bit ALUs, which means it has about 60% of the memory and 250 times as many ALUs as a server-class CPU, despite being half its size and power (see [Section 7.9](#)). Compared to a server-class GPU, the TPU has 3.5 times the on-chip memory and 25 times as many ALUs.
3. *Use the easiest form of parallelism that matches the domain.*
The TPU delivers its performance via a two-dimensional SIMD parallelism with its 256×256 Matrix Multiply Unit, which is internally pipelined with a systolic organization, plus a simple overlapped execution pipeline of its

instructions. GPUs rely instead on multiprocessing, multithreading, and one-dimensional SIMD, and CPUs rely on multiprocessing, out-of-order execution, and one-dimensional SIMD.

4. *Reduce data size and type to the simplest needed for the domain.*

The TPU computes primarily on 8-bit integers, although it supports 16-bit integers and accumulates in 32-bit integers. CPUs and GPUs also support 64-bit integers and 32-bit and 64-bit floating point.

5. *Use a domain-specific programming language to port code to the DSA.*

The TPU is programmed using the TensorFlow programming framework, whereas GPUs rely on CUDA and OpenCL and CPUs must run virtually everything.

7.5

Microsoft Catapult, a Flexible Data Center Accelerator

At the same time that Google was thinking about deploying a custom ASIC in its data centers, Microsoft was considering accelerators for theirs. The Microsoft perspective was that any solution had to follow these guidelines:

- It had to preserve homogeneity of servers to enable rapid redeployment of machines and to avoid making maintenance and scheduling even more complicated, even if that notion is a bit at odds with the concept of DSAs.
- It had to scale to applications that might need more resources than could fit into a single accelerator without burdening all applications with multiple accelerators.
- It needed to be power-efficient.
- It couldn't become a dependability problem by being a single point of failure.
- It had to fit within the available spare space and power in existing servers.
- It could not hurt data center network performance or reliability.
- The accelerator had to improve the cost-performance of the server.

The first rule prevented deploying an ASIC that helped only some applications on some servers, which was the decision that Google made.

Microsoft started a project called Catapult that placed an FPGA on a PCIe bus board into data center servers. These boards have a dedicated network for applications that need more than one FPGA. The plan was to use the flexibility of the FPGA to tailor its use for varying applications both on different servers and to reprogram the same server to accelerate distinct applications over time. This plan increased the return on its investment of the accelerator. Another advantage of FPGAs is that they should have lower NRE than ASICs, which could again improve return on investment. We discuss two generations of Catapult, showing how the design evolved to meet the needs of WSCs.

One interesting upside of FPGAs is that each application—or even each phase of an application—can be thought of as its own DSA, so in this section, we get to see many examples of novel architectures in one hardware platform.

Catapult Implementation and Architecture

Figure 7.19 shows a PCIe board that Microsoft designed to fit within its servers, which limited power and cooling to 25 W. This constraint led to the selection of the 28-nm Altera Stratix V D5 FPGA for its first implementation of Catapult. The board also has 32 MiB of flash memory and includes two banks of DDR3-1600 DRAM with a total capacity of 8 GiB. The FPGA has 3926 18-bit ALUs, 5 MiB of on-chip memory, and 11 GB/s bandwidth to DDR3 DRAMs.

Figure 7.19 The Catapult board design. (A) shows the block diagram, and (B) is a photograph of both sides of the board, which is 10 cm × 9 cm × 16 mm. The PCIe and inter-FPGA network are wired to a connector on the bottom of the board that plugs directly into the motherboard. (C) is a photograph of the server, which is 1U (4.45 cm) high and half a standard rack wide. Each server has two 12-core Intel Sandy Bridge Xeon CPUs, 64 GiB of DRAM, 2 solid-state drives, 4 hard-disk drives, and a 10-Gbit Ethernet network card. The highlighted rectangle on the right in (C) shows the location of the Catapult FPGA board on the server. The cool air is sucked in from the left in (C), and the hot air exhausts to the right, which passes over the Catapult board. This hot spot and the amount of the power that the connector could deliver mean that the Catapult board is limited to 25 watts. Forty-eight servers share an Ethernet switch that connects to the data center network, and they occupy half of a data center rack.

Each of the 48 servers in half of a data center rack contains a Catapult board. Catapult follows the preceding guidelines about supporting applications that need more than a single FPGA without affecting the performance of the data center network. It adds a separate low-latency 20 Gbit/s network that connects 48 FPGAs. The network topology is a two-dimensional 6×8 torus network.

To follow the guideline about not being a single point of failure, this network can be reconfigured to operate even if one of the FPGAs fails. The board also has SECEDED protection on all memories outside the FPGA, which is required for large-scale deployment in a data center.

Because FPGAs use a great deal of memory on the chip to deliver programmability, they are more vulnerable than ASICs to *single-event upsets (SEUs)* because of radiation as the process geometries shrink. The Altera FPGA in Catapult boards includes mechanisms to detect and correct SEUs inside the FPGA and reduces the chances of SEUs by periodically scrubbing the FPGA configuration state.

The separate network has an added benefit of reducing the variability of communication performance as compared to a data center network. Network unpredictability increases tail latency—which is especially detrimental for applications that face end users—so a separate network makes it easier to successfully offload work from the CPU to the accelerator. This FPGA network can run a much simpler protocol than in the data center because the error rates are considerably lower and the network topology is well defined.

Note that resiliency requires care when reconfiguring FPGAs so that they neither appear as failed nodes nor crash the host server or corrupt their neighbors. Microsoft developed a high-level protocol for ensuring safety when reconfiguring one or more FPGAs.

Catapult Software

Possibly the biggest difference between Catapult and the TPU is having to program in a hardware-description language such as Verilog or VHDL. As the Catapult authors write ([Putnam et al., 2016](#)):

Going forward, the biggest obstacle to widespread adoption of FPGAs in the datacenter is likely to be programmability. FPGA development still requires extensive hand-coding in Register Transfer Level and manual tuning.

To reduce the burden of programming Catapult FPGAs, the Register Transfer Level (RTL) code is divided into the *shell* and the *role*, as [Figure 7.20](#) shows. The shell code is like the system library on an embedded CPU. It contains the RTL code that will be reused across applications on the same FPGA board, such as data marshaling, CPU-to-FPGA communication, FPGA-to-FPGA communication, data movement, reconfiguration, and health monitoring. The shell RTL code is 23% of the Altera FPGA. The role code is the application logic, which the Catapult programmer writes using the remaining 77% of the FPGA resources. Having a shell has the added benefit of offering a standard API and standard behavior across applications.

Figure 7.20 Components of Catapult shell and role split of the RTL code.

CNNs on Catapult

Microsoft developed a configurable CNN accelerator as an application for Catapult. Configuration parameters include the number of neural network layers, the dimension of those layers, and even the numerical precision to be used. Figure 7.21 shows the block diagram of the CNN accelerator. Its key features are:

- Run-time configurable design, without requiring recompilation using the FPGA tools.
- To minimize memory accesses, it offers efficient buffering of CNN data structures (see Figure 7.21).
- A two-dimensional array of Processing Elements (PEs) that can scale up to thousands of units.

Figure 7.21 CNN Accelerator for Catapult. The Input Volume of the left correspond to Layer[$i-1$] on the left of Figure 7.20, with NumFM[$i-1$] corresponding to *y* and DimFM[$i-1$] corresponding to *z*. Output Volume at the top maps to Layer[i], with *z* mapping to NumFM[i] and DimFM[i] mapping to *x*. The next figure shows the inside of the Processing Element (PE).

Images are sent to DRAM and then input into a multibank buffer in the FPGA. The inputs are sent to multiple PEs to perform the stencil computations that produce the output feature maps. A controller (upper left in Figure 7.21) orchestrates the flow of data to each PE. The final results are then recirculated to the input buffers to compute the next layer of the CNN.

Like the TPU, the PEs are designed to be used as a systolic array. Figure 7.22 shows the details of the PE design.

Search Acceleration on Catapult

The primary application to test the return on investment of Catapult was a critical function of the Microsoft Bing search engine called *ranking*. It ranks the order of the results from a search. The output is a document score, which determines the position of the document on the web page that is presented to the user. The algorithm has three stages:

1. *Feature Extraction* extracts thousands of interesting features from a document based on the search query, such as the frequency that the query phrase appears in a document.
2. *Free-Form Expressions* calculates thousands of combinations of features from the prior stage.
3. *Machine-Learned Scoring* uses machine-learning algorithms to evaluate the features from the first two stages to calculate a floating-point score of a document that is returned to the host search software.

The Catapult implementation of ranking produces identical results to equivalent Bing software, even reproducing known bugs!

Taking advantage of one of the preceding guidelines, the ranking function does not have to fit within a single FPGA. Here is how the ranking stages are split across eight FPGAs:

- One FPGA does Feature Extraction.
- Two FPGAs do Free-Form Expressions.
- One FPGA does a compression stage that increases scoring engine efficiency.
- Three FPGA do Machine-Learned Scoring.

The remaining FPGA is a spare used to tolerate faults. Using multiple FPGAs for one application works well because of the dedicated FPGA network.

Figure 7.23 shows the Feature Extraction stage organization. It uses 43 feature-extraction state machines to compute in parallel 4500 features per document-query pair.

Next is the following Free-Form Expressions stage. Rather than implement the functions directly in gates or in state machines, Microsoft developed a 60-core processor that overcomes long-latency operations with multithreading. Unlike a GPU, Microsoft's processor does not require SIMD execution. It has three features that let it match the latency target:

1. Each core supports four simultaneous threads where one can stall on a long operation but the others can continue. All functional units are pipelined, so they can accept a new operation every clock cycle.
2. Threads are statically prioritized using a priority encoder. Expressions with the longest latency use thread slot 0 on all cores, then the next slowest is in slot 1 on all cores, and so on.

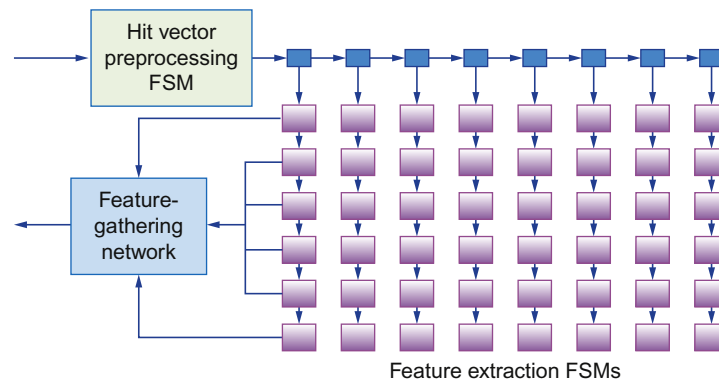

Figure 7.23 The architecture of FPGA implementation of the Feature Extraction stage. A hit vector, which describes the locations of query words in each document, is streamed into the hit vector preprocessing state machine and then split into control and data tokens. These tokens are issued in parallel to the 43 unique feature state machines. The feature-gathering network collects generated feature and value pairs and forwards them to the following Free-Form Expressions stage.

- Expressions that are too large to fit in the time allocated for a single FPGA can be split across the two FPGAs used for free-form expressions.

One cost of the reprogrammability in an FPGA is a slower clock rate than custom chips. Machine-Learned Scoring uses two forms of parallelism to try to overcome that disadvantage. The first is to have a pipeline that matches the available pipeline parallelism in the application. For ranking, the limit is 8 μ s per stage. The second version of parallelism is the rarely seen *multiple instruction streams, single data stream (MISD)* parallelism, where a large number of independent instruction streams operate in parallel on a single document.

Figure 7.24 shows the performance of the ranking function on Catapult. As we will see in Section 7.9, user-facing applications often have rigid response times; it doesn't matter how high the throughput is if the application misses the deadline. The *x*-axis shows the response-time limit, with 1.0 as the cutoff. At this maximum latency, Catapult is 1.95 times as fast as the host Intel server.

Catapult Version 1 Deployment

Before populating a whole warehouse-scale computer with tens of thousands of servers, Microsoft did a test deployment of 17 full racks, which contained $17 \times 48 \times 2$ or 1632 Intel servers. The Catapult cards and network links were tested at manufacture and system integration, but at deployment, seven of the 1632 cards failed (0.43%), and one of the 3264 FPGA network links (0.03%) was defective. After several months of deployment, nothing else failed.

Figure 7.24 Performance for the ranking function on Catapult for a given latency bound. The x-axis shows the response time for the Bing ranking function. The maximum response time at the 95th percentile for the Bing application on the x-axis is 1.0, so data points to the right may have a higher throughput but arrive too late to be useful. The y-axis shows the 95% throughputs on Catapult and pure software for a given response time. At a normalized response time of 1.0, Catapult has 1.95 the throughput of Intel server running in pure software mode. Stated alternatively, if Catapult matches the throughput that the Intel server has at 1.0 normalized response time, Catapult’s response time is 29% less.

Catapult Version 2

Although the test deployment was successful, Microsoft changed the architecture for the real deployment to enable both Bing and Azure Networking to use the same boards and architecture (Caulfield et al., 2016). The main problem with the V1 architecture was that the independent FPGA network did not enable the FPGA to see and process standard Ethernet/IP packets, which prevented it from being used to accelerate the data center network infrastructure. In addition, the cabling was expensive and complicated, it was limited to 48 FPGAs, and the rerouting of traffic during certain failure patterns reduced performance and could isolate nodes.

The solution was to place the FPGA logically between the CPU and NIC, so that all network traffic goes through the FPGA. This “bump-on-a-wire” placement removes many weaknesses of the FPGA network in Catapult V1. Moreover, it enables the FPGAs to run their own low-latency network protocol that allows them to be treated as a global pool of all the FPGAs in the data center and even across data centers.

Three changes occurred between V1 and V2 to overcome the original concerns of Catapult applications interfering with data center network traffic. First, the data center network was upgraded from 10 Gbit/s to 40 Gbit/s, increasing the headroom. Second, Catapult V2 added a rate limiter for FPGA logic, ensuring that an FPGA application could not overwhelm the network. The final and perhaps most

important change was that the networking engineers would now have their own use cases for the FPGA, given its bump-in-the-wire placement. That placement transformed these former interested bystanders into enthusiastic collaborators.

By deploying Catapult V2 in the majority of its new servers, Microsoft essentially has a second supercomputer composed of distributed FPGAs that shares the same network wires as the CPU servers and is at the same scale, as there is one FPGA per server. Figures 7.25 and 7.26 show the block diagram and the board for Catapult V2.

Catapult V2 follows the same shell and role split of the RTL to simplify programming, but at the time of publication, the shell uses almost half of the FPGA resources (44%) because of the more complicated network protocol that shares the data center network wires.

Catapult V2 is used for both Ranking acceleration and function network acceleration. In Ranking acceleration, rather than perform nearly all of the ranking function inside the FPGA, Microsoft implemented only the most compute-intensive portions and left the rest to the host CPU:

- The *feature functional unit (FFU)* is a collection of finite state machines that measure standard features in search, such as counting the frequency of a particular search term. It is similar in concept to the Feature Extraction stage of Catapult V1.

Figure 7.25 The Catapult V2 block diagram. All network traffic is routed through the FPGA to the NIC. There is also a PCIe connector to the CPUs, which allows the FPGA to be used as a local compute accelerator, as in Catapult V1.

Figure 7.26 The Catapult V2 board uses a PCIe slot. It uses the same FPGA as Catapult V1 and has a TDP of 32 W. A 256-MB Flash chip holds the *golden image* for the FPGA that is loaded at power on, as well as one application image.

- The *dynamic programming feature (DPF)* creates a Microsoft proprietary set of features using dynamic programming and bears some similarity to the Free-Form Expressions stage of Catapult V1.

Both are designed so that they can use non-local FPGAs for these tasks, which simplifies scheduling.

Figure 7.27 shows the performance of Catapult V2 compared to software in a format similar to Figure 7.24. The throughput can now be increased $2.25\times$ without endangering latency, whereas the speedup was previously $1.95\times$. When ranking was deployed and measured in production, Catapult V2 had better tail latencies than software; that is, the FPGA latencies never exceeded the software latencies at any given demand despite being able to absorb twice the workload.

Summary: How Catapult Follows the Guidelines

Microsoft reported that adding Catapult V1 to the servers in the pilot phase increased the total cost of ownership (TCO) by less than 30%. Thus, for this application, the net gain in cost-performance for Ranking was at least $1.95/1.30$, or a return on investment of about 1.5. Although no comment was made about TCO concerning Catapult V2, the board has a similar number of the same type of chips, so we might guess that the TCO is no higher. If so, the cost-performance of Catapult V2 is about $2.25/1.30$, or 1.75 for Ranking.

Here is how Catapult followed the guidelines from Section 7.2.

Figure 7.27 Performance for the ranking function on Catapult V2 in the same format as [Figure 7.24](#). Note that this version measures 99th percentile while the earlier figure plots 95th percentile.

1. *Use dedicated memories to minimize the distance over which data is moved.*
The Altera V FPGA has 5 MiB of memory on-chip, which an application can customize for its use. For example, for CNNs, it is used for the input and output feature maps of [Figure 7.21](#).
2. *Invest the resources saved from dropping advanced microarchitectural optimizations into more arithmetic units or bigger memories.*
The Altera V FPGA also has 3926 18-bit ALUs that are tailored to the application. For CNNs, they are used to create the systolic array that drives the Processing Elements in [Figure 7.22](#), and they form the datapaths of the 60-core multiprocessor used by Free Form Expression stage of ranking.
3. *Use the easiest form of parallelism that matches the domain.*
Catapult picks the form of parallelism that matches the application. For example, Catapult uses two-dimensional SIMD parallelism for the CNN application and MISD parallelism in the Machine Scoring phase stream Ranking.
4. *Reduce data size and type to the simplest needed for the domain.*
Catapult can use whatever size and type of data that the application wants, from an 8-bit integer to a 64-bit floating point.
5. *Use a domain-specific programming language to port code to the DSA.*
In this case, programming is done in the hardware register-transfer language (RTL) Verilog, which is an even less productive language than C or C++. Microsoft did not (and possibly could not) follow this guideline given its use of FPGAs.

Although this guideline concerns the one-time porting of an application from software to FPGA, applications are not frozen in time. Almost by definition, software evolves to add features or fix bugs, especially for something as important as web search.

Maintenance of successful programs can be most of software's development costs. Moreover, when programming in an RTL, software maintenance is even more burdensome. The Microsoft developers, like all others who use FPGAs as accelerators, hope that future advances in domain-specific languages and systems for hardware-software co-design will reduce the difficulty of programming FPGAs.

7.6

Intel Crest, a Data Center Accelerator for Training

The quotation by the Intel CEO that opens [Section 7.3](#) came from the press release announcing that Intel was going to start shipping DSAs (“accelerants”) for DNN. The first example was Crest, which was announced while we were writing this edition. Despite the limited details, we include it here because of the significance of a traditional microprocessor manufacturer like Intel taking this bold step of embracing DSAs.

Crest is aimed at DNN training. The Intel CEO said the goal is to accelerate DNN training a hundredfold over the next three years. [Figure 7.6](#) shows that training can take a month. There is likely to be a demand to decrease the DNN training to just eight hours, which would be 100 times quicker than the CEO predicted. DNNs will surely become even more complex over the next 3 years, which will require a much greater training effort. Thus there seems little danger that a $100\times$ improvement in training is overkill.

Crest instructions operate on blocks of 32×32 matrices. Crest uses a number format called *flex point*, which is a scaled fixed-point representation: 32×32 matrices of 16-bit data share a single 5-bit exponent that is provided as part of the instruction set.

[Figure 7.28](#) shows the block diagram of the Lake Crest chip. To compute on these matrices, Crest uses the 12 processing clusters of [Figure 7.28](#). Each cluster includes a large SRAM, a big linear algebra processing unit, and a small amount of logic for on- and off-chip routing. The four 8 GiB HBM2 DRAM modules offer 1 TB/s of memory bandwidth, which should lead to an attractive Roofline model for the Crest chip. In addition to high-bandwidth paths to main memory, Lake Crest supports high bandwidth interconnects directly between compute cores inside the processing clusters, which facilitates quick core-to-core communication without passing through shared memory. Lake Crest's goal is a factor of 10 improvement in training over GPUs.

[Figure 7.28](#) shows 12 Inter-Chip Links (ICLs) and 2 Inter-Chip Controllers (ICCs), so Crest is clearly designed to allow many Crest chips to collaborate, similar in spirit to the dedicated network connecting the 48 FPGAs in Catapult. It's likely that the $100\times$ improvement in training will require ganging together several Crest chips.

7.7

Pixel Visual Core, a Personal Mobile Device Image Processing Unit

Pixel Visual Core is a programmable, scalable DSA intended for image processing and computer vision from Google, initially for cell phones and tablets running the

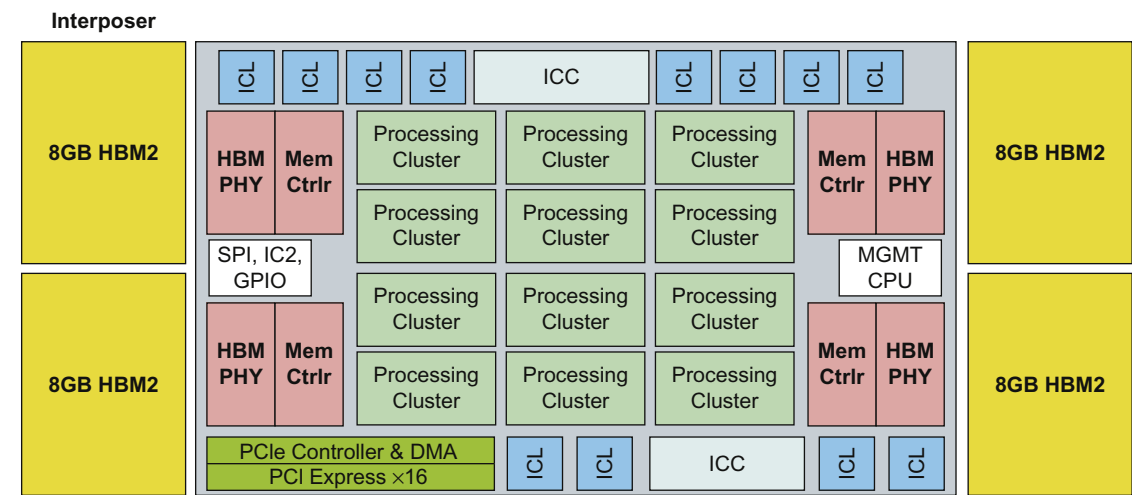

Figure 7.28 Block diagram of the Intel Lake Crest processor. Before being acquired by Intel, Crest said that the chip is almost a full reticle in TSMC 28 nm, which would make the die size 600–700 mm². This chip should be available in 2017. Intel is also building Knights Crest, which is a hybrid chip containing Xeon x86 cores and Crest accelerators.

Android operating system, and then potentially for Internet of Things (IoT) devices. It is a multicore design, supporting between 2 and 16 cores to deliver a desired cost-performance. It is designed either to be its own chip or to be part of a *system on a chip* (SOC). It has a much smaller area and energy budget than its TPU cousin. [Figure 7.29](#) lists terms and acronyms found in this section.

Pixel Visual Core is an example of a new class of domain specific architectures for vision processing that we call *image processing units* (IPUs). IPUs solve the inverse problem of GPUs: they analyze and modify an input image in contrast to generating an output image. We call them IPUs to signal that, as a DSA, they do not need to do everything well because there will also be CPUs (and GPUs) in the system to perform non-input-vision tasks. IPUs rely on stencil computations mentioned above for CNNs.

The innovations of Pixel Visual Core include replacing the one-dimensional SIMD unit of CPUs with a two-dimensional array of processing elements (PEs). They provide a two-dimensional shifting network for the PEs that is aware of the two-dimensional spatial relationship between the elements, and a two-dimensional version of buffers that reduces accesses to off-chip memory. This novel hardware makes it easy to perform stencil computations that are central to both vision processing and CNN algorithms.

ISPs, the Hardwired Predecessors of IPUs

Most portable mobile devices (PMDs) have multiple cameras for input, which has led to hardwired accelerators called *image signal processors* (ISPs) for enhancing

Term	Acronym	Short explanation
Core	–	A processor. Pixel Visual Core can have 2–16 cores. The first implementation has 8; also called <i>stencil processor (STP)</i>
Halide	–	A domain-specific programming language for image processing that separates the algorithm from its execution schedule
Halo	–	An extended region around the 16×16 computation array to handle stencil computation near the borders of the array. It holds values, but doesn't compute
Image signal processors	ISP	A fixed function ASIC that improves the visual quality of an image; found in virtually all PMDs with cameras
Image processing unit	IPU	A DSA that solves the inverse problem of a GPU: it analyzes and modifies an <i>input</i> image in contrast to generating an <i>output</i> image
Line buffer pool	LB	A line buffer is designed to capture a sufficient number of full lines of an intermediate image to keep the next stage busy. Pixel Visual Core uses two-dimensional line buffers, each Change 64 to 128 KiB. The <i>Line Buffer Pool</i> contains one LB per core plus one LB for DMA
Network on chip	NOC	The network that connects the cores in Pixel Visual Core
Physical ISA	pISA	The Pixel Visual Core instruction set architecture (ISA) that is executed by the hardware
Processing element array	–	The 16×16 array of Processing Elements plus the halo that performs the 16-bit multiply-add operations. Each Processing Element includes a Vector Lane and local memory. It can shift data en masse to neighbors in any of four directions
Sheet generator	SHG	Does memory accesses of blocks of 1×1 to 31×31 pixels, which are called <i>sheets</i> . The different sizes allow the option of including the space for the halo or not
Scalar lane	SCL	Same operations as the Vector Lane except it adds instructions that handle jumps, branches, and interrupts, controls instruction flow to the vector array, and schedules all the loads and stores for the sheet generator. It also has a small instruction memory. It plays the same role as the scalar processor in a vector architecture
Vector lane	VL	Portion of the Processing Element that performs the computer arithmetic
Virtual ISA	vISA	The Pixel Visual Core ISA generated by the compiler. It is mapped to pISA before execution

Figure 7.29 A handy guide to Pixel Visual Core terms in [Section 7.7](#). [Figure 7.4](#) on page 437 has a guide for [Sections 7.3–7.6](#).

input images. The ISP is usually a fixed function ASIC. Virtually every PMD today includes an ISP.

[Figure 7.30](#) shows a typical organization of an image-processing system, including the lens, sensor, ISP, CPU, DRAM, and display. The ISP receives images, removes artifacts in images from the lens and the sensor, interpolates missing colors, and significantly improves the overall visual quality of the image. PMDs tend to have small lens and thus tiny noisy pixels, so this step is critical to producing high-quality photos and videos.

An ISP processes the input image in raster scan order by calculating a series of cascading algorithms via software configurable hardware building blocks, typically organized as a pipeline to minimize memory traffic. At each stage of the pipeline and for each clock cycle, a few pixels are input, and a few are output. Computation is typically performed over small neighborhoods of pixels (*stencils*). Stages are connected by buffers called *line buffers*. The line buffers help

Figure 7.30 Diagram showing interconnection of the Image Signal Processor (ISP), CPU, DRAM, lens, and sensor. The ISP sends statistics to the CPU as well as the improved image either to the display or to DRAM for storage or later processing. The CPU then processes the image statistics and sends information to let the system adapt: *Auto White Balance* (AWB) to the ISP, *Auto Exposure* (AE) to the sensor, and *Auto Focus* (AF) to the lens, known as the 3As.

keep the processing stages utilized via spatial locality by capturing just enough full lines of an intermediate image to facilitate the computation required by the next stage.

The enhanced image is either sent to a display or to DRAM for storage or for later processing. The ISP also sends statistics about the image (e.g., color and luma histograms, sharpness, and so on) to the CPU, which in turn it processes and sends information to help the system adapt.

Although efficient, ISPs have two major downsides. Given the increasing demand for improved image quality in handheld devices, the first is the inflexibility of an ISP, especially as it takes years to design and manufacture a new ISP within an SOC. The second is that these computing resources can be used only for the image-enhancing function, no matter what is needed at the time on the PMD. Current generation ISPs handle workloads at up to 2 Tera-operations per second on a PMD power budget, so a DSA replacement has to achieve similar performance and efficiency.

Pixel Visual Core Software

Pixel Visual Core generalized the typical hardwired pipeline organization of kernels of an ISP into a *directed acyclic graph (DAG)* of kernels. Pixel Visual Core image-processing programs are typically written in Halide, which is a domain-specific functional programming language for image processing. [Figure 7.31](#) is a Halide example that blurs an image. Halide has a functional section to express the function being programmed and a separate schedule section to specify how to optimize that function to the underlying hardware.

```

Func buildBlur(Func input) {
    // Functional portion (independent of target processor)
    Func blur_x("blur_x"), blur_y("blur_y");
    blur_x(x,y) = (input(x-1,y) + input(x,y)*2 + input(x+1,y)) / 4;
    blur_y(x,y) = (blur_x(x,y-1) + blur_x(x,y)*2 + blur_x(x,y+1)) / 4;

    if (has_ipu) {
        // Schedule portion (directs how to optimize for target processor)
        blur_x.ipu(x,y);
        blur_y.ipu(x,y);
    }
    return blur_y;
}

```

Figure 7.31 Portion of a Halide example to blur an image. The `ipu(x,y)` suffix schedules the function to Pixel Visual Core. A blur has the effect of looking at the image through a translucent screen, which reduces noise and detail. A Gaussian function is often used to blur the image.

Pixel Visual Core Architecture Philosophy

The power budget of PMDs is 6–8 W for bursts of 10–20 seconds, dropping down to tens of milliwatts when the screen is off. Given the challenging energy goals of a PMD chip, the Pixel Visual Core architecture was strongly shaped by the relative energy costs for the primitive operations mentioned in [Chapter 1](#) and made explicit in [Figure 7.32](#). Strikingly, a single 8-bit DRAM access takes as much energy as 12,500 8-bit additions or 7–100 8-bit SRAM accesses, depending on the organization of the SRAM. The $22\times$ to $150\times$ higher cost of IEEE 754 floating-point operations over 8-bit integer operations, plus the die size and energy benefits of storing narrower data, strongly favor using narrow integers whenever algorithms can accommodate them.

In addition to the guidelines from [Section 7.2](#), these observations led to other themes that guided the Pixel Visual Core design:

- *Two-dimensional is better than one-dimensional:* Two-dimensional organizations can be beneficial for processing images as it minimizes communication distance and because the two- and three-dimensional nature of image data can utilize such organizations.
- *Closer is better than farther:* Moving data is expensive. Moreover, the relative cost of moving data to an ALU operation is increasing. And of course DRAM time and energy costs far exceed any local data storage or movement.

A primary goal in going from an ISP to an IPU is to get more reuse of the hardware via programmability. Here are the three main features of the Pixel Visual Core:

Operation	Energy (pJ)	Operation	Energy (pJ)	Operation	Energy (pJ)
8b DRAM LPDDR3	125.00	8b SRAM	1.2–17.1	16b SRAM	2.4–34.2
32b Fl. Pt. muladd	2.70	8b int muladd	0.12	16b int muladd	0.43
32b Fl. Pt. add	1.50	8b int add	0.01	16b int add	0.02

Figure 7.32 Relative energy costs per operation in picoJoules assuming TSMC 28-nm HPM process, which was the process Pixel Visual Core used [17][18][19][20]. The absolute energy cost are less than in Figure 7.2 because of using 28 nm instead of 90 nm, but the relative energy costs are similarly high.

1. Following the theme that two-dimensional is better than one-dimensional, Pixel Visual Core uses a two-dimensional SIMD architecture instead of one-dimensional SIMD architecture. Thus it has a two-dimensional array of independent *processing elements* (PEs), each of which contains 2 16-bit ALUs, 1 16-bit MAC unit, 10 16-bit registers, and 10 1-bit predicate registers. The 16-bit arithmetic follows the guideline of providing only the precision needed by the domain.
2. Pixel Visual Core needs temporary storage at each PE. Following the guideline from Section 7.2 of avoiding caches, this PE memory is a compiler-managed scratchpad memory. The logical size of each PE memory is 128 entries of 16 bits, or just 256 bytes. Because it would be inefficient to implement a separate small SRAM in each PE, Pixel Visual Core instead groups the PE memory of 8 PEs together in a single wide SRAM block. Because the PEs operate in SIMD fashion, Pixel Visual Core can bind all the individual reads and writes together to form a “squarer” SRAM, which is more efficient than narrow and deep or wide and shallow SRAMs. Figure 7.33 shows four PEs.
3. To be able to perform simultaneous stencil computations in all PEs, Pixel Visual Core needs to collect inputs from nearest neighbors. This communication pattern requires a “NSEW” (North, South, East, West) shift network: it can shift data en masse between the PEs in any compass direction. So that it doesn’t lose pixels along the edges as it shifts images, Pixel Visual Core connects the end-points of the network together to form a torus.

Note that the shift network is in contrast with the systolic array of processing element arrays in the TPU and Catapult. In this case, software explicitly moves the data in the desired direction across the array, whereas the systolic approach is a hardware-controlled, two-dimensional pipeline that moves data as a wavefront that is invisible to the software.

The Pixel Visual Core Halo

A 3×3 , 5×5 , or 7×7 stencil is going to get inputs from 1, 2, or 3 external pixels at the edges of the two-dimensional subset being computed (half of the dimension of the stencil minus one-half). That leaves two choices. Either Pixel Visual Core

Figure 7.33 The two-dimensional SIMD includes two-dimensional shifting “N,” “S,” “E,” “W,” show the direction of the shift (North, South, East, West). Each PE has a software-controlled scratchpad memory.

under utilizes the hardware in the elements near the border, because they only pass input values, or Pixel Visual Core slightly extends the two-dimensional PEs with simplified PEs that leave out the ALUs. Because the difference in size between a standard PE and a simplified PE is about $2.2 \times$, Pixel Visual Core has an extended array. This extended region is called the *halo*. Figure 7.34 shows two rows of a halo surrounding an 8×8 PE array and illustrates how an example 5×5 stencil computation in the upper-left corner relies on the halo.

A Processor of the Pixel Visual Core

The collection of 16×16 PEs and 4 halo lanes in each dimension, called the *PE array* or *vector array*, is the main computation unit of the Pixel Visual Core. It also has a load-store unit called a *Sheet Generator (SHG)*. SHG refers to memory accesses of blocks of 1×1 to 256×256 pixels, which are called *sheets*. This happens during downsampling, and typical values are 16×16 or 20×20 .

An implementation of Pixel Visual Core can have any even number of 2 or more cores, depending on the resources available. Thus it needs a network to connect them together, so every core also has an interface to the Network on Chip (NOC). A typical NOC implementation for Pixel Visual Core will not be an expensive cross switch, however, because those require data to travel a long distance, which is expensive. Leveraging the pipeline nature of the application, the NOC typically needs to communicate only to neighboring cores. It is implemented as a two-dimensional mesh, which allows power gating of pairs of cores under software control.

Figure 7.34 The two-dimensional array of full processing elements (shown as unshaded circles) surrounded by two layers of simplified processing elements (shaded diamonds) called a halo. In this figure, there are 8×8 or 64 full PEs with 80 simplified PEs in the halo. (Pixel Visual Core actually has 16×16 or 256 full PEs and two layers in its halo and thus 144 simplified PEs.) The edges of the halo are connected (shown as gray lines) to form a torus. Pixel Visual Core does a series of two-dimensional shifts across all processing elements to move the neighbor portions of each stencil computation into the center PE of the stencil. An example 5×5 stencil is shown in the upper-left corner. Note that 16 of the 25 pieces of data for this 5×5 stencil location come from halo processing elements.

Finally, the Pixel Visual Core also includes a scalar processor that is called a *scalar lane (SCL)*. It is identical to the vector lane, except it adds instructions that handle jumps, branches, and interrupts, controls instruction flow to the vector array, and schedules all the loads and stores for the sheet generator. It also has a small instruction memory. Note that Pixel Visual Core has a single instruction stream that controls the scalar and vector units, similar to how a CPU core has a single instruction stream for its scalar and SIMD units.

In addition to cores, there is also a DMA engine to transfer data between DRAM and the line buffers while efficiently converting between image memory layout formats (e.g., packing/unpacking). As well as sequential DRAM accesses, the DMA engines perform vector-like gather reads of DRAM as well as sequential and strided reads and writes.

Pixel Visual Core Instruction Set Architecture

Like GPUs, Pixel Visual Core uses a two-step compilation process. The first step is compiling the programs from the target language (e.g., Halide) into *vISA* instructions. The Pixel Visual Core *vISA* (*virtual Instruction Set Architecture*) is inspired in part by the RISC-V instruction set, but it uses an image-specific memory model and extends the instruction set to handle image processing, and in particular, the two-dimensional notion of images. In *vISA*, the two-dimensional array of a core is infinite, the number of register is unbounded, and memory size is similarly unlimited. *vISA* instructions contain pure functions that don't directly access DRAM (see [Figure 7.36](#)), which greatly simplifies mapping them onto the hardware.

The next step is to compile the *vISA* program into a *pISA* (*physical Instruction Set Architecture*) program. Using *vISA* as the target of compilers allows the processor to be software-compatible with past programs and yet accept changes to the *pISA* instruction set, so *vISA* plays the same role that PTX does for GPUs (see [Chapter 4](#)).

Lowering from *vISA* to *pISA* takes two steps: compilation and mapping with early-bound parameters, and then patching the code with late-bound parameters. The parameters that must be bound include STP size, halo size, number of STPs, mapping of line buffers, mapping of kernels to processors, as well as register and local memory allocations.

[Figure 7.35](#) shows that *pISA* is a very long instruction word (VLIW) instruction set with 119-bit-wide instructions. The first 43-bit field is for the Scalar Lane, the next 38-bit field specifies the computation by the two-dimensional PE array, and the third 12-bit field specifies the memory accesses by the two-dimensional PE array. The last two fields are immediates for computation or addressing. The operations for all the VLIW fields are what you'd expect: two's complement integer arithmetic, saturating integer arithmetic, logical operations, shifts, data transfers, and a few special ones like divide iteration and count leading zeros. The Scalar Lane supports a superset of the operations in the two-dimensional PE array, plus it adds instructions for control-flow and sheet-generator control. The 1-bit Predicate registers mentioned above enables conditional moves to registers (e.g., $A = B$ if C).

Field	Scalar	Math	Memory	Imm	MemImm
# Bits	43	38	12	16	10

Figure 7.35 VLIW format of the 119-bit *pISA* instruction.

Although the pISA VLIW instruction is very wide, Halide kernels are short, often just 200–600 instructions. Recall that as an IPU, it only needs to execute the compute-intensive portion of an application, leaving the rest of the functionality to CPUs and GPUs. Thus the instruction memory of a Pixel Visual Core holds just 2048 pISA instructions (28.5 KiB).

The Scalar Lane issues sheet generator instructions that access line buffers. Unlike other memory accesses within Pixel Visual Core, the latency can be more than 1 clock cycle, so they have a DMA-like interface. The lane first sets up the addresses and transfer size in special registers.

Pixel Visual Core Example

Figure 7.36 shows the vISA code that is output from the Halide compiler for the blur example in Figure 7.31, with comments added for clarity. It calculates a blur first in the x direction and then in the y direction using 16-bit arithmetic. The vISA code matches the functional part of the Halide program. This code can be thought of as executing across all the pixels of an image.

Pixel Visual Core Processing Element

One of the architectural decisions was how big to build the halo. Pixel Visual Core uses 16×16 PEs, and it adds a halo of 2 extra elements, so it can support 5×5

```
// vISA inner loop blur in x dimension

```

Figure 7.36 Portion of the vISA instructions compiled from the Halide Blur code in Figure 7.31. This vISA code corresponds to the functional part of the Halide code.

stencils directly. Note that the bigger the array of PEs, the less the halo overhead to support a given stencil size.

For Pixel Visual Core, the smaller size of the halo PEs and the 16×16 arrays means it only costs 20% more area for the halo. For a 5×5 stencil, Pixel Visual Core can calculate 1.8 times as many results per clock cycle ($16^2/12^2$), and the ratio is 1.3 for a 3×3 stencil ($16^2/14^2$).

The design of the arithmetic unit of the PE is driven by multiply-accumulate (MAC), which is a primitive of stencil computation. Pixel Visual Core native MACs are 16-bits wide for the multiplies, but they can accumulate at a 32-bit width. Pipelining MAC would use energy unnecessarily because of the reading and writing of the added pipeline register. Thus the multiply-add hardware determines the clock cycle. The other operations, previously mentioned, are the traditional logical and arithmetic operations along with saturating versions of the arithmetic operations and a few specialized instructions.

The PE has two 16-bit ALUs that can operate in a variety of ways within a single clock cycle:

- Independently, producing two 16-bit results: $A \text{ op } B, C \text{ op } D$.
- Fused, producing just one 16-bit result: $A \text{ op } (C \text{ op } D)$.
- Joined, producing one 32-bit result: $A:C \text{ op } B:D$.

Two-Dimensional Line Buffers and Their Controller

Because DRAM accesses use so much energy (see [Figure 7.32](#)), the Pixel Visual Core memory system was carefully designed to minimize the number of DRAM accesses. The key innovation is the *two-dimensional line buffer*.

Kernels are logically running on separate cores, and they are connected in a DAG with input from the sensor or DRAM and output to DRAM. The line buffers hold portions of the image being calculated between kernels. [Figure 7.37](#) shows the logical use of line buffers in Pixel Visual Core.

Figure 7.37 Programmer view of Pixel Visual Core: a directed-acyclic graph of kernels.

Here are four features that the two-dimensional line buffer must support:

1. It must support two-dimensional stencil computations of various sizes, which are unknown at design time.
2. Because of the halo, for the 16×16 PE array in Pixel Visual Core, the STPs will want to read 20×20 blocks of pixels from the line buffer and write 16×16 blocks of pixels to the line buffer. (As previously mentioned, they call these blocks of pixels *sheets*.)
3. Because the DAG is programmable, we need line buffers that can be allocated by software between any two cores.
4. Several cores may need to read data from the same line buffer. Thus a line buffer should support multiple consumers, although it needs just one producer.

Line buffers in Pixel Visual Core are really a multi-reader, two-dimensional FIFO abstraction on top of a relatively large amount of SRAM: 128 KiB per instance. It contains temporary “images” that are used just once, so a small, dedicated local FIFO is much more efficient than a cache for data in distant memory.

To accommodate the size mismatch between reading 20×20 blocks of pixels and writing 16×16 blocks, the fundamental unit of allocation in the FIFO is a group of 4×4 pixels. Per stencil processor, there is one *Line Buffer Pool (LBP)* that can have eight logical line buffers (*LB*), plus one LBP for DMA of I/O. The LBP has three levels of abstraction:

1. At the top, the LBP controller supports eight LBs as logical instances. Each LB has one FIFO producer and up to eight FIFO consumers per LB.
2. The controller keeps track of a set of head and tail pointers for each FIFO. Note that the sizes of the line buffers inside the LBP are flexible and up to the controller.
3. At the bottom are many physical memory banks to support the bandwidth requirements. Pixel Visual Core has eight physical memory banks, each having a 128-bit interface and 16 KiB of capacity.

The controller for the LBP is challenging because it must fulfill the bandwidth demands of the STPs and I/O DMAs as well as schedule all their reads and writes to the banks of physical SRAM memory. The LBP controller is one of the most complicated pieces of Pixel Visual Core.

Pixel Visual Core Implementation

The first implementation of Pixel Visual Core was as a separate chip. [Figure 7.38](#) shows the floorplan of the chip, which has 8 cores. It was fabricated in a TSMC 28 nm technology in 2016. The chip dimensions are 6×7.2 mm, it runs at 426 MHz, it is stacked with 512 MB DRAM as Silicon in Package, and consumes

Figure 7.38 Floor plan of the 8-core Pixel Visual Core chip. A53 is an ARMv7 core. LPDDR4 is a DRAM controller. PCIe and MIPI are I/O buses.

(including the DRAM) 187–4500 mW depending on the workload. About 30% of the power for the chip is for an ARMv7 A53 core for control, the MIPI, the PCIe, the LPDDR interfaces, interface is just over half this die at 23 mm². Power for Pixel Visual Core running a worst case “power virus” can go as high as 3200 mW. [Figure 7.39](#) shows the floor plan of a core.

Summary: How Pixel Visual Core Follows the Guidelines

Pixel Visual Core is a multicore DSA for image and vision processing intended as a stand-alone chip or as an IP block for mobile device SOCs. As we will see in [Section 7.9](#), its performance per watt for CNNs are factors of 25–100 better than CPUs and GPUs. Here is how the Pixel Visual core followed the guidelines in [Section 7.2](#).

1. *Use dedicated memories to minimize the distance over which data is moved.*
Perhaps the most distinguishing architecture feature of Pixel Visual Core is the software-controlled, two-dimensional line buffers. At 128 KiB per core, they are a significant fraction of the area. Each core also has 64 KiB of software-controlled PE memory for temporary storage.
2. *Invest the resources saved from dropping advanced microarchitectural optimizations into more arithmetic units or bigger memories.*
Two other key features of Pixel Visual Core are a 16×16 two-dimensional array of processing elements per core and a two-dimensional shifting network between the processing elements. It offers a halo region that acts as a buffer to allow full utilization of its 256 arithmetic units.

Figure 7.39 Floor plan of a Pixel Visual Core. From left to right, and top down: the scalar lane (SCL) is 4% of the core area, NOC is 2%, the line buffer pool (LBP) is 15%, the sheet generator (SHG) is 5%, the halo is 11%, and the processing element array is 62%. The torus connection of the halo makes each of the four edges of the array logical neighbors. It is more area-efficient to collapse the halo to just two sides, which preserves the topology.

3. *Use the easiest form of parallelism that matches the domain.*

Pixel Visual Core relies on two-dimensional SIMD parallelism using its PE array, VLIW to express instruction-level parallelism, and multiple program multiple data (MPMD) parallelism to utilize multiple cores.

4. *Reduce data size and type to the simplest needed for the domain.*

Pixel Visual Core relies primarily on 8-bit and 16-bit integers, but it also works with 32-bit integers, albeit more slowly.

5. *Use a domain-specific programming language to port code to the DSA.*

Pixel Visual Core is programmed in the domain-specific language Halide for image processing and in TensorFlow for CNNs.

7.8

Cross-Cutting Issues

Heterogeneity and System on a Chip (SOC)

The easy way to incorporate DSAs into a system is over the I/O bus, which is the approach of the data center accelerators in this chapter. To avoid fetching memory operands over the slow I/O bus, these accelerators have local DRAM.

Amdahl's Law reminds us that the performance of an accelerator is limited by the frequency of shipping data between the host memory and the accelerator memory. There will surely be applications that would benefit from the host CPU and the accelerators to be integrated into the same *system on a chip (SOC)*, which is one of the goals of Pixel Visual Core and eventually the Intel Crest.

Such a design is called an *IP block*, standing for *Intellectual Property*, but a more descriptive name might be portable design block. IP blocks are typically specified in a hardware description language like Verilog or VHDL to be integrated into the SOC. IP blocks enable a marketplace where many companies make IP blocks that other companies can buy to build the SOC for their applications without having to design everything themselves. Figure 7.40 indicates the importance of IP blocks by plotting the number of IP blocks across generations of Apple PMD SOC; they tripled in just four years. Another indication of the importance of IP blocks is that the CPU and GPU get only one-third of the area of the Apple SOC, with IP blocks occupying the remainder (Shao and Brooks, 2015).

Designing an SOC is like city planning, where independent groups lobby for limited resources, and finding that the right compromise is difficult. CPUs, GPUs, caches, video encoders, and so on have adjustable designs that can shrink or expand to use more or less area and energy to deliver more or less performance. Budgets will differ depending on whether the SOC is for tablets or for IoT. Thus an IP block must be scalable in area, energy, and performance. Moreover, it is especially important for a new IP block to offer a small resource version because it may not already have a well-established foothold in the SOC ecosystem; adoption is much easier if the initial resource request can be modest. The Pixel Visual Core approach is a multicore design, allowing the SOC engineer to choose between 2 and 16 cores to match the area and power budget and desired performance.

Figure 7.40 Number of IP blocks in Apple SOC for the iPhone and iPad between 2010 and 2014 (Shao and Brooks, 2015).

It will be interesting to see whether the attractiveness of integration leads to most data center processors coming from traditional CPU companies with IP accelerators integrated into the CPU die, or whether systems companies will continue designing their own accelerators and include IP CPUs in their ASICs.

An Open Instruction Set

One challenge for designers of DSAs is determining how to collaborate with a CPU to run the rest of the application. If it's going to be on the same SOC, then a major decision is which CPU instruction set to choose, because until recently virtually every instruction set belonged to a single company. Previously, the practical first step of an SOC was to sign a contract with a company to lock in the instruction set.

The alternative was to design your own custom RISC processor and to port a compiler and libraries to it. The cost and hassle of licensing IP cores led to a surprisingly large number of do-it-yourself simple RISC processors in SOCs. One AMD engineer estimated that there were 12 instruction sets in a modern microprocessor!

RISC-V offers a third choice: a viable free and open instruction set with plenty of opcode space reserved for adding instructions for domain-specific coprocessors, which enables the previously mentioned tighter integration between CPUs and DSAs. SOC designers can now select a standard instruction set that comes with a large base of support software without having to sign a contract.

They still have to pick the instruction set early in the design, but they don't have to pick one company and sign a contract. They can design a RISC-V core themselves, they can buy one from the several companies that sell RISC-V IP blocks, or they can download one of the free open-source RISC-V IP blocks developed by others. The last case is analogous to open-source software, which offers web browsers, compilers, operating systems, and so on that volunteers maintain for users to download and use for free.

As a bonus, the open nature of the instruction set improves the business case for small companies offering RISC-V technology because customers don't have to worry about the long-term viability of a company with its own unique instruction set.

Another attraction of RISC-V for DSAs is that the instruction set is not as important as it is for general-purpose processors. If DSAs are programmed at higher levels using abstractions like DAGs or parallel patterns, as is the case for Halide and TensorFlow, then there is less to do at the instruction set level. Moreover, in a world where performance-cost and energy-cost advances come from adding DSAs, binary compatibility may not play as important a role as in the past.

At the time of this writing, the future of the open RISC-V instruction set appears promising. (We wish we could peer into the future and learn the status of RISC-V from now to the next edition of this book!)

7.9

Putting It All Together: CPUs Versus GPUs Versus DNN Accelerators

We now use the DNN domain to compare the cost-performance of the accelerators in this chapter.² We start with a thorough comparison of the TPU to standard CPUs and GPUs and then add brief comparisons to Catapult and Pixel Visual Core.

Figure 7.41 shows the six benchmarks we use in this comparison. They consist of two examples of each of the three types of DNNs in Section 7.3. These six benchmarks represent 95% of TPU inference workload in Google data centers in 2016. Typically written in TensorFlow, they are surprisingly short: just 100–1500 lines of code. They are small pieces of larger applications that run on the host server, which can be thousands to millions of lines of C++ code. The applications are typically user-facing, which leads to rigid response-time limits, as we will see.

Figures 7.42 and 7.43 show the chips and servers being compared. They are server-class computers deployed in Google data centers at the same time that TPUs were deployed. To be deployed in Google data centers, they must at least check for internal memory errors, which excluded some choices, such as the Nvidia Maxwell GPU. For Google to purchase and deploy them, the machines had to be sensibly configured, and not awkward artifacts assembled solely to win benchmarks.

The traditional CPU server is represented by an 18-core, dual-socket Haswell processor from Intel. This platform is also the host server for GPUs or TPUs.

Name	LOC	DNN layers						TPU Ops/Weight	% deployed TPUs 2016
		FC	Conv	Element	Pool	Total	Weights		
MLP0	100	5				5	20M	200	61%
MLP1	1000	4				4	5M	168	
LSTM0	1000	24		34		58	52M	64	29%
LSTM1	1500	37		19		56	34M	96	
CNN0	1000		16			16	8M	2888	5%
CNN1	1000	4	72		13	89	100M	1750	

Figure 7.41 Six DNN applications (two per DNN type) that represent 95% of the TPU’s workload. The 10 columns are the DNN name; the number of lines of code; the types and number of layers in the DNN (FC is fully connected; Conv is convolution; Element is element-wise operation of LSTM, see Section 7.3; and Pool is pooling, which is a downsizing stage that replaces a group of elements with its average or maximum); the number of weights; TPU operational intensity; and TPU application popularity in 2016. The operational intensity varies between TPU, CPU, and GPU because the batch sizes vary. The TPU can have larger batch sizes while still staying under the response time limit. One DNN is RankBrain (Clark, 2015), one LSTM is GNM Translate (Wu et al., 2016), and one CNN is DeepMind AlphaGo (Silver et al., 2016; Jouppi, 2016).

²This section is also largely based upon the paper “In-Datacenter Performance Analysis of a Tensor Processing Unit” Jouppi et al., 2017, of which one of your book authors was a coauthor.

Chip model	mm ²	nm	MHz	TDP	Measured		TOPS/s		GB/s	On-chip memory
					Idle	Busy	8b	FP		
Intel Haswell	662	22	2300	145W	41W	145W	2.6	1.3	51	51 MiB
NVIDIA K80	561	28	560	150W	25W	98W	–	2.8	160	8 MiB
TPU	<331*	28	700	75W	28W	40W	92	–	34	28 MiB

*The TPU die size is less than half of the Haswell die size.

Figure 7.42 The chips used by the benchmarked servers are Haswell CPUs, K80 GPUs, and TPUs. Haswell has 18 cores, and the K80 has 13 SMX processors.

Server	Dies/Server	DRAM	TDP	Measured power	
				Idle	Busy
Intel Haswell	2	256 GiB	504W	159W	455W
NVIDIA K80 (2 dies/card)	8	256 GiB (host) + 12 GiB × 8	1838W	357W	991W
TPU	4	256 GiB (host) + 8 GiB × 4	861W	290W	384W

Figure 7.43 Benchmarked servers that use the chips in [Figure 7.42](#). The low-power TPU allows for better rack-level density than the high-power GPU. The 8 GiB DRAM per TPU is Weight Memory.

Haswell is fabricated in an Intel 22-nm process. Both the CPU and GPU are very large dies: about 600 mm²!

The GPU accelerator is the Nvidia K80. Each K80 card contains two dies and offers SECCED on internal memory and DRAM. Nvidia states that ([Nvidia, 2016](#))

the K80 Accelerator dramatically lowers datacenter cost by delivering application performance with fewer, more powerful servers.

DNN researchers frequently used K80s in 2015, which is when they were deployed at Google. Note that K80s were also chosen for new cloud-based GPUs by Amazon Web Services and by Microsoft Azure in late 2016.

Because the number of dies per benchmarked server varies between 2 and 8, the following figures show results normalized per die, except for [Figure 7.50](#), which compares the performance/watt of whole servers.

Performance: Rooflines, Response Time, and Throughput

To illustrate the performance of the six benchmarks on the three processors, we adapt the Roofline performance model in [Chapter 4](#). To use the Roofline model for the TPU, when DNN applications are quantized, we first replace floating-point operations with integer multiply-accumulate operations. As weights do not normally fit in on-chip memory for DNN applications, the second change is to redefine operational intensity to be integer operations per byte of weights read ([Figure 7.41](#)).

Figure 7.44 TPU Roofline. Its ridge point is far to the right at 1350 multiply-accumulate operations per byte of weight memory. CNN1 is much further below its Roofline than the other DNNs because it spends about a third of the time waiting for weights to be loaded into the matrix unit and because the shallow depth of some layers in the CNN results in only half of the elements within the matrix unit holding useful values (Jouppi et al., 2017).

Figure 7.44 shows the Roofline model for a single TPU on log-log scales. The TPU has a long “slanted” part of its Roofline, where operational intensity means that performance is limited by memory bandwidth rather than by peak compute. Five of the six applications are happily bumping their heads against the ceiling: the MLPs and LSTMs are memory-bound, and the CNNs are computation-bound. The single DNN that is not bumping its head against the ceiling is CNN1. Despite CNNs having very high operational intensity, CNN1 is running at only 14.1 Tera Operations Per Second (TOPS), while CNN0 runs at a satisfying 86 TOPS.

For readers interested into a deep dive into what happened with CNN1, Figure 7.45 uses performance counters to give partial visibility into the utilization of the TPU. The TPU spends less than half of its cycles performing matrix operations for CNN1 (column 7, row 1). On each of those active cycles, only about half of the 65,536 MACs hold useful weights because some layers in CNN1 have shallow feature depths. About 35% of cycles are spent waiting for weights to load from memory into the matrix unit, which occurs during the four fully connected layers that run at an operational intensity of just 32. This leaves roughly 19% of cycles not

Application	MLP0	MLP1	LSTM0	LSTM1	CNN0	CNN1	Mean	Row
Array active cycles	12.7%	10.6%	8.2%	10.5%	78.2%	46.2%	28%	1
Useful MACs in 64K matrix (% peak)	12.5%	9.4%	8.2%	6.3%	78.2%	22.5%	23%	2
Unused MACs	0.3%	1.2%	0.0%	4.2%	0.0%	23.7%	5%	3
Weight stall cycles	53.9%	44.2%	58.1%	62.1%	0.0%	28.1%	43%	4
Weight shift cycles	15.9%	13.4%	15.8%	17.1%	0.0%	7.0%	12%	5
Non-matrix cycles	17.5%	31.9%	17.9%	10.3%	21.8%	18.7%	20%	6
RAW stalls	3.3%	8.4%	14.6%	10.6%	3.5%	22.8%	11%	7
Input data stalls	6.1%	8.8%	5.1%	2.4%	3.4%	0.6%	4%	8
TeraOp/s (92 Peak)	12.3	9.7	3.7	2.8	86.0	14.1	21.4	9

Figure 7.45 Factors limiting TPU performance of the NN workload based on hardware performance counters. Rows 1, 4, 5, and 6 total 100% and are based on measurements of activity of the matrix unit. Rows 2 and 3 further break down the fraction of 64K weights in the matrix unit that hold useful weights on active cycles. Our counters cannot exactly explain the time when the matrix unit is idle in row 6; rows 7 and 8 show counters for two possible reasons, including RAW pipeline hazards and PCIe input stalls. Row 9 (TOPS) is based on measurements of production code while the other rows are based on performance-counter measurements, so they are not perfectly consistent. Host server overhead is excluded here. The MLPs and LSTMs are memory-bandwidth limited, but CNNs are not. CNN1 results are explained in the text.

explained by the matrix-related counters. Because of overlapped execution on the TPU, we do not have exact accounting for those cycles, but we can see that 23% of cycles have stalls for RAW dependences in the pipeline and that 1% are spent stalled for input over the PCIe bus.

Figures 7.46 and 7.47 show Rooflines for Haswell and the K80. The six NN applications are generally further below their ceilings than the TPU in Figure 7.44. Response-time limits are the reason. Many of these DNN applications are parts of services that are part of end-user-facing services. Researchers have demonstrated that small increases in response time cause customers to use a service less (see Chapter 6). Thus, although training may not have hard response-time deadlines, inference usually does. That is, inference cares about throughput only while it is maintaining the latency bound.

Figure 7.48 illustrates the impact of the 99th percentile response-time limit of 7 ms for MLP0 on Haswell and the K80, which was required by the application developer. (The inferences per second and 7-ms latency include the server host time as well as the accelerator time.) They can operate at 42% and 37%, respectively, with the highest throughput achievable for MLP0, if the response-time limit is relaxed. Thus, although CPUs and GPUs have potentially much higher throughput, it's wasted if they don't meet the response-time limit. These bounds affect the TPU as well, but at 80% in Figure 7.48, it is operating much closer to its highest MLP0 throughput. As compared with CPUs and GPUs, the single-threaded TPU has none of the sophisticated microarchitectural features discussed in Section 7.1 that consume transistors and energy to improve the average case but not the 99th-percentile case.

Figure 7.46 Intel Haswell CPU Roofline with its ridge point at 13 multiply-accumulate operations/byte, which is much further to the left than in Figure 7.44.

Figure 7.47 NVIDIA K80 GPU die Roofline. The much higher memory bandwidth moves the ridge point to 9 multiply-accumulate operations per weight byte, which is even further to the left than in Figure 7.46.

Figure 7.49 gives the bottom line of relative inference performance per die, including the host server overhead for the two accelerators. Recall that architects use the geometric mean when they don't know the actual mix of programs that will be run. For this comparison, however, we *do* know the mix (Figure 7.41). The

Type	Batch	99th% response	Inf/s (IPS)	% max IPS
CPU	16	7.2 ms	5482	42%
CPU	64	21.3 ms	13,194	100%
GPU	16	6.7 ms	13,461	37%
GPU	64	8.3 ms	36,465	100%
TPU	200	7.0 ms	225,000	80%
TPU	250	10.0 ms	280,000	100%

Figure 7.48 99th% response time and per die throughput (IPS) for MLP0 as batch size varies. The longest allowable latency is 7 ms. For the GPU and TPU, the maximum MLP0 throughput is limited by the host server overhead.

Type	MLP0	MLP1	LSTM0	LSTM1	CNN0	CNN1	Mean
GPU	2.5	0.3	0.4	1.2	1.6	2.7	1.9
TPU	41.0	18.5	3.5	1.2	40.3	71.0	29.2
Ratio	16.7	60.0	8.0	1.0	25.4	26.3	15.3

Figure 7.49 K80 GPU and TPU performance relative to CPU for the DNN workload. The mean uses the actual mix of the six applications in [Figure 7.41](#). Relative performance for the GPU and TPU includes host server overhead. [Figure 7.48](#) corresponds to the second column of this table (MLP0), showing relative IPS that meet the 7-ms latency threshold.

weighted mean in the last column of [Figure 7.49](#) using the actual mix makes the GPU up to 1.9 times, and the TPU is 29.2 times as fast as the CPU, so the TPU is 15.3 times as fast as the GPU.

Cost-Performance, TCO, and Performance/Watt

When buying computers by the thousands, cost-performance trumps general performance. The best cost metric in a data center is total cost of ownership (TCO). The actual price Google pays for thousands of chips depends on negotiations between the companies involved. For business reasons, Google can't publish such price information or data that might let them be deduced. However, power is correlated with TCO, and Google can publish watts per server, so we use performance/watt as our proxy for performance/TCO. In this section, we compare servers ([Figure 7.43](#)) rather than single dies ([Figure 7.42](#)).

[Figure 7.50](#) shows the weighted mean performance/watt for the K80 GPU and TPU relative to the Haswell CPU. We present two different calculations of performance/watt. The first ("total") includes the power consumed by the host CPU server when calculating performance/watt for the GPU and TPU. The second ("incremental") subtracts the host CPU server power from the total for the GPU and TPU beforehand.

Figure 7.50 Relative performance/watt of GPU and TPU servers to CPU or GPU servers. Total performance/watt includes host server power, but incremental doesn't. It is a widely quoted metric, but we use it as a proxy for performance/TCO in the data center.

For total-performance/watt, the K80 server is $2.1 \times$ Haswell. For incremental-performance/watt, when Haswell power is omitted, the K80 server is $2.9 \times$.

The TPU server has 34 times better total-performance/watt than Haswell, which makes the TPU server 16 times the performance/watt of the K80 server. The relative incremental-performance/watt—which was Google's justification for a custom ASIC—is 83 for the TPU, which lifts the TPU to 29 times the performance/watt of the GPU.

Evaluating Catapult and Pixel Visual Core

Catapult V1 runs CNNs $2.3 \times$ as fast as a 2.1 GHz, 16-core, dual-socket server (Ovtcharov et al., 2015a). Using the next generation of FPGAs (14-nm Arria 10), performance goes up $7 \times$, and perhaps even $17 \times$ with more careful floorplanning and scaling up of the Processing Elements (Ovtcharov et al., 2015b). In both cases, Catapult increases power by less than $1.2 \times$. Although it's apples versus oranges, the TPU runs its CNNs $40 \times$ to $70 \times$ versus a somewhat faster server (see Figures 7.42, 7.43, and 7.49).

Because Pixel Visual Core and the TPU are both made by Google, the good news is that we can directly compare performance for CNN1, which is a common DNN, although it had to be translated from TensorFlow. It runs with batch size of 1 instead of 32 as in the TPU. The TPU runs CNN1 about 50 times as fast as Pixel Visual Core, which makes Pixel Visual Core about half as fast as the GPU and a little faster than Haswell. Incremental performance/watt for CNN1 raises Pixel Visual Core to about half the TPU, 25 times the GPU, and 100 times the CPU.

Because the Intel Crest is designed for training rather than inference, it wouldn't be fair to include it in this section, even if it were available to measure.

7.10

Fallacies and Pitfalls

In these early days of both DSAs and DNNs, fallacies abound.

Fallacy *It costs \$100 million to design a custom chip.*

Figure 7.51 shows a graph from an article that debunks the widely quoted \$100-million myth that it was “only” \$50 million, with most of the cost being salaries (Olofsson, 2011). Note that the author's estimate is for sophisticated processors that include features that DSAs by definition omit, so even if there were no improvement to the development process, you would expect the cost of a DSA design to be less.

Why are we more optimistic six years later, when, if anything, mask costs are even higher for the smaller process technologies?

First, software is the largest category, at almost a third of the cost. The availability of applications written in domain-specific languages allows the compilers to do most of the work of porting the applications to your DSA, as we saw for the TPU and Pixel Visual Core. The open RISC-V instruction set will also help reduce the cost of getting system software as well as cut the large IP costs.

Mask and fabrication costs can be saved by having multiple projects share a single reticle. As long as you have a small chip, amazingly enough, for \$30,000 anyone can get 100 untested parts in 28-nm TSMC technology (Patterson and Nikolić, 2015).

Figure 7.51 The breakdown of the \$50 million cost of a custom ASIC that came from surveying others (Olofsson, 2011). The author wrote that his company spent just \$2 million for its ASIC.

Perhaps the biggest change is to hardware engineering, which is more than a quarter of the cost. Hardware engineers have begun to follow their software colleagues to use agile development. The traditional hardware process not only has separate phases for design requirements, architecture, logical design, layout, verification, and so on, but also it uses different job titles for the people who perform each of the phases. This process is heavy on planning, documentation, and scheduling in part because of the change in personnel each phase.

Software used to follow this “waterfall” model as well, but projects were so commonly late, over budget, and even canceled that it led to a radically different approach. The Agile Manifesto in 2001 basically said that it was much more likely that a small team that iterated on an incomplete but working prototype shown regularly to customers would produce useful software on schedule and on budget more than the traditional plan-and-document approach of the waterfall process would.

Small hardware teams now do agile iterations (Lee et al., 2016). To ameliorate the long latency of a chip fabrication, engineers do some iterations using FPGAs because modern design systems can produce both the EDIF for FPGAs and chip layout from a single design. FPGA prototypes run 10–20 times slower than chips, but that is still much faster than simulators. They also do “tape-in” iterations, where you do all the work of a tape-out for your working but incomplete prototype, but you don’t pay the costs of fabricating a chip.

In addition to an improved development process, more modern hardware design languages to support them (Bachrach et al., 2012), and advances in automatic generation of hardware from high-level domain-specific languages (Canis et al., 2013; Huang et al., 2016; Prabhakar et al., 2016). Open source cores that you can download for free and modify should also lower the cost of hardware design.

Pitfall *Performance counters added as an afterthought for DSA hardware.*

The TPU has 106 performance counters, and the designers wanted even more (see Figure 7.45). The *raison d’être* for DSAs is performance, and it is way too early in their evolution to have a good idea about what is going on.

Fallacy *Architects are tackling the right DNN tasks.*

The architecture community is paying attention to deep learning: 15% of the papers at ISCA 2016 were on hardware accelerators for DNNs! Alas, all nine papers looked at CNNs, and only two mentioned other DNNs. CNNs are more complex than MLPs and are prominent in DNN competitions (Russakovsky et al., 2015), which might explain their allure, but they are only about 5% of the Google data center NN workload. It seems wise try to accelerate MLPs and LSTMs with at least as much gusto.

Fallacy *For DNN hardware, inferences per second (IPS) is a fair summary performance metric.*

IPS is not appropriate as a single, overall performance summary for DNN hardware because it’s simply the inverse of the complexity of the typical inference in the application (e.g., the number, size, and type of NN layers). For example, the

TPU runs the 4-layer MLP1 at 360,000 IPS but the 89-layer CNN1 at only 4700 IPS; thus TPU IPS varies by 75X! Therefore using IPS as the single-speed summary is much more misleading for NN accelerators than MIPS or FLOPS is for traditional processors, so IPS should be even more disparaged. To compare DNN machines better, we need a benchmark suite written at a high level to port it to the wide variety of DNN architectures. Fathom is a promising new attempt at such a benchmark suite ([Adolf et al., 2016](#)).

Pitfall *Being ignorant of architecture history when designing a DSA.*

Ideas that didn't fly for general-purpose computing may be ideal for DSAs, thus history-aware architects could have a competitive edge. For the TPU, three important architectural features date back to the early 1980s: systolic arrays ([Kung and Leiserson, 1980](#)), decoupled-access/execute ([Smith, 1982b](#)), and CISC instructions ([Patterson and Ditzel, 1980](#)). The first reduced the area and power of the large Matrix Multiply Unit, the second fetched weights concurrently during operation of the Matrix Multiply Unit, and the third better utilized the limited bandwidth of the PCIe bus for delivering instructions. We advise mining the historical perspectives sections at the end of every chapter of this book to discover jewels that could embellish DSAs that you design.

7.11

Concluding Remarks

In this chapter, we've seen several commercial examples of the recent shift from the traditional goal of improving general-purpose computers so that all programs benefit to accelerating a subset of programs with DSAs.

Both versions of Catapult preserved data-center homogeneity by designing a small, low-power FPGA board that could fit inside a server. The hope is that the flexibility of FPGAs will allow Catapult to be useful to many current applications and the new ones that appeared after deployment. Catapult runs search rank and CNNs faster than GPUs, offering a 1.5–1.75 gain in performance/TCO for ranking over CPUs.

The TPU project actually began with FPGAs but abandoned them when the designers concluded that the FPGAs of that time were not competitive in performance compared to the GPUs. They also believed the TPU would use much less power than GPUs, while being as fast or faster, potentially making the TPU much better than FPGAs and GPUs. Finally, the TPU was not the device that broke data center homogeneity at Google because some servers in its data centers already had GPUs. The TPU basically followed in the footsteps of the GPU and was just another type of accelerator.

The nonrecurring engineering costs were likely much higher for the TPU than for Catapult, but the rewards were also greater: both performance and performance/watt were much higher for an ASIC than for an FPGA. The risk was that the TPU was appropriate only for DNN inference, but as we mentioned, DNNs are an attractive target because they can potentially be used for many applications. In 2013

Google’s management took a leap of faith by trusting that the DNN requirements in 2015 and beyond would justify investment in the TPU.

The deterministic execution model of both Catapult and the TPU is a better match to the response-time deadline of user-facing applications than are the time-varying optimizations of CPUs and GPUs (caches, out-of-order execution, multithreading, multiprocessing, prefetching, etc.) that help average throughput more than latency. The lack of such features helps explain why, despite having myriad ALUs and a big memory, the TPU is relatively small and low powered. This achievement suggests a “Cornucopia Corollary” to Amdahl’s Law: *low utilization of a huge, cheap resource can still deliver high, cost-effective performance.*

In summary, the TPU succeeded for DNNs because of the large matrix unit; the substantial software-controlled on-chip memory; the ability to run whole inference models to reduce dependence on host CPU; a single-threaded, deterministic execution model that proved to be a good match to 99th-percentile response-time limits; enough flexibility to match the DNNs of 2017 as well as of 2013; the omission of general-purpose features that enabled a small and low-power die despite the larger datapath and memory; the use of 8-bit integers by the quantized applications; and the fact that applications were written using TensorFlow, which made it easy to port them to the DSA at high-performance rather than having to rewrite them in order for them to run well on the very different hardware.

Pixel Visual Core demonstrated the constraints of designing a DSA for a PMD in terms of die size and power. Unlike the TPU, it is a separate processor from the host that fetches its own instructions. Despite being aimed primarily at computer vision, Pixel Visual Core can run CNNs one to two orders of magnitude better in performance/watt than the K80 GPU and the Haswell CPU.

It’s too early to render judgment on the Intel Crest, although its enthusiastic announcement by the Intel CEO signals a shift in the computing landscape.

An Architecture Renaissance

For at least the past decade, architecture researchers have been publishing innovations based on simulations using limited benchmarks claiming improvements for general-purpose processors of *10% or less* while companies are now reporting gains for DSA hardware products of *10 times or more*.

We think that is a sign that the field is undergoing a transformation, and we expect to see a renaissance in architecture innovation in the next decade because of

- the historic end of both Dennard scaling and Moore’s Law, which means improving cost-energy-performance will require innovation in computer architecture;
- the productivity advances in building hardware from both Agile hardware development and new hardware design languages that leverage advances in modern programming languages;

- the reduced cost of hardware development because of free and open instruction sets, open-source IP blocks, and commercial IP blocks (which so far is where most DSAs are found);
- the improvements mentioned above in productivity and cost of development means researchers can afford to demonstrate their ideas by building them in FPGAs or even in custom chips, instead of trying to convince skeptics with simulators; and
- the potential upside of DSAs and their synergy with domain-specific programming languages.

We believe that many architecture researchers will build DSAs that will raise the bar still higher than those discussed in this chapter. And we can't wait to see what the computer architecture world will look like by the next edition of this book!

7.12

Historical Perspectives and References

Section M.9 (available online) covers the development of DSAs.

Case Studies and Exercises by Cliff Young

Case Study: Google's Tensor Processing Unit and Acceleration of Deep Neural Networks

Concepts illustrated by this case study

- Structure of matrix multiplication operations
- Capacities of memories and rates of computations ("speeds and feeds") for a simple neural network model
- Construction of a special-purpose ISA
- Inefficiencies in mapping convolutions to TPU hardware
- Fixed-point arithmetic
- Function approximation

- 7.1 [10/20/10/25/25] <7.3,7.4> Matrix multiplication is a key operation supported in hardware by the TPU. Before going into details of the TPU hardware, it's worth analyzing the matrix multiplication calculation itself. One common way to depict matrix multiplication is with the following triply nested loop:

```
float a[M][K], b[K][N], c[M][N];
// M, N, and K are constants.
for (int i = 0; i < M; ++i)
    for (int j = 0; j < N; ++j)
        for (int k = 0; k < K; ++k)
            c[i][j] += a[i][k] * b[k][j];
```

- a. [10] Suppose that M , N , and K are all equal. What is the asymptotic complexity in time of this algorithm? What is the asymptotic complexity in space of the arguments? What does this mean for the operational intensity of matrix multiplication as M , N , and K grow large?
- b. [20] Suppose that $M=3$, $N=4$, and $K=5$, so that each of the dimensions are relatively prime. Write out the order of accesses to memory locations in each of the three matrices A , B , and C (you might start with two-dimensional indices, then translate those to memory addresses or offsets from the start of each matrix). For which matrices are the elements accessed sequentially? Which are not? Assume row-major (C-language) memory ordering.
- c. [10] Suppose that you transpose matrix B , swapping its indices so that they are $B[N][K]$ instead. So, now the innermost statement of the loop looks like:

```
c[i][j] += a[i][k] * b[j][k];
```

Now, for which matrices are the elements accessed sequentially?

- d. [25] The innermost (k -indexed) loop of our original routine performs a dot-product operation. Suppose that you are given a hardware unit that can perform an 8-element dot-product more efficiently than the raw C code, behaving effectively like this C function:

```
void hardware_dot(float *accumulator,
    const float *a_slice, const float *b_slice) {
    float total = 0.;
    for (int k = 0; k < 8; ++k) {
        total += a_slice[k] * b_slice[k];
    }
    *accumulator += total;
}
```

How would you rewrite the routine with the transposed B matrix from part (c) to use this function?

- e. [25] Suppose that instead, you are given a hardware unit that performs an 8-element “saxpy” operation, which behaves like this C function:

```
void hardware_saxpy(float *accumulator,
    float a, const float *input) {
    for (int k = 0; k < 8; ++k) {
        accumulator[k] += a * input[k];
    }
}
```

Write another routine that uses the saxpy primitive to deliver equivalent results to the original loop, without the transposed memory ordering for the B matrix.

- 7.2 [15/10/10/20/15/15/20/20] <7.3,7.4> Consider the neural network model MLP0 from [Figure 7.5](#). That model has 20 M weights in five fully connected layers (neural network researchers count the input layer as if it were a layer in the stack, but it has no

weights associated with it). For simplicity, let's assume that those layers are each the same size, so each layer holds 4 M weights. Then assume that each layer has identical geometry, so each group of 4 M weights represents a $2\text{ K} \times 2\text{ K}$ matrix. Because the TPU typically uses 8-bit numerical values, 20 M weights take up 20 MB.

- a. [15] For batch sizes of 128, 256, 512, 1024, and 2048, how big are the input activations for each layer of the model (which, except for the input layer, are also the output activations of the previous layer)? Now considering the whole mode (i.e., there's just the input to the first layer and the output from the last layer), for each batch size, what is the transfer time for input and output over PCIe Gen3 x16, which has a transfer speed of about 100 Gbit/s?
- b. [10] Given the memory system speed of 30 GiB/s, give a lower bound for the time the TPU takes to read the weights of MLP0 from memory. How much time does it take for the TPU to read a 256×256 “tile” of weights from memory?
- c. [10] Show how to calculate the TPU's 92 T operations/second, given that we know that the systolic array matrix multiplier has 256×256 elements, each of which performs an 8-bit multiply-accumulate operation (MAC) each cycle. In high-performance-computing marketing terms, a MAC counts as two operations.
- d. [20] Once a weight tile has been loaded into the matrix unit of the TPU, it can be reused to multiply a 256-element input vector by the 256×256 weight matrix represented by the tile to produce a 256-element output vector every cycle. How many cycles pass during the time it takes to load a weight tile? This is the “break-even” batch size, where compute and memory-load times are equal, also known as the “ridge” of the roofline.
- e. [15] The compute peak for the Intel Haswell x86 server is about 1 T FLOPS, while the compute peak for the NVIDIA K80 GPU is about 3 T FLOPS. Supposing that they hit these peak numbers, calculate their best-case compute time for batch size 128. How do these times compare to the time the TPU takes to load all 20 M weights from memory?
- f. [15] Assuming that the TPU program does not overlap computation with I/O over PCIe, calculate the time elapsed from when the CPU starts to send the first byte of data to the TPU until the time that the last byte of output is returned. What fraction of PCIe bandwidth is used?
- g. [20] Suppose that we deployed a configuration where one CPU was connected to five TPUs across a single PCIe Gen3 x16 bus (with appropriate PCIe switches). Assume that we parallelize by placing one layer of MLP0 on each TPU, and that the TPUs can communicate directly with each other over PCIe. At batch = 128, what is the best-case latency for calculating a single inference, and what throughput, in terms of inferences per second, would such a configuration deliver? How does this compare to a single TPU?
- h. [20] Suppose that each example in a batch of inferences requires 50 core-microseconds of processing time on the CPU. How many cores on the host CPU will be required to drive a single-TPU configuration at batch = 128?

7.3 [20/25/25/25/Discussion] <7.3,7.4> Consider a pseudo-assembly language for the TPU, and consider the program that handles a batch of size 2048 for a tiny fully

connected layer with a 256×256 weight matrix. If there were no constraints on the sizes or alignments of computations in each instruction, the entire program for that layer might look like the following:

```
read_host u#0, 256*2048
read_weights w#0, 256*256
// matmul weights are implicitly read from the FIFO.
activate u#256*2048, a#0, 256*2048
write_host, u#256*2048, 256*2048
```

In this pseudo-assembly language, a prefix of “u#” refers to a memory address in the unified buffer; a prefix of “w#” refers to a memory address in the off-chip weight DRAM, and a prefix of “a#” refers to an accumulator address. The last argument of each assembly instruction describes the number of bytes to be operated upon.

Let’s walk through the program instruction by instruction:

- The read_host instruction reads 512 KB of data from host memory, storing it at the very beginning of the unified buffer (u#0).
- The read_weights instruction tells the weight fetching unit to read 64 KB of weights, loading them into the on-chip weight FIFO. These 64 KB of weights represent a single, 256×256 matrix of weights, which we will call a “weight tile.”
- The matmul instruction reads the 512 KB of input data from address 0 in the unified buffer, performs a matrix multiplication with the tile of weights, and stores the resulting $256*2048=524,288$, 32-bit activations at accumulator address 0 (a#0). We have intentionally glossed over the details of the ordering of weights; the exercise will expand on these details.
- The activate instruction takes those 524,288 32-bit accumulators at a#0, applies an activation function to them, and stores the resulting 524,288, 8-bit output values at the next free location in the unified buffer, u#524288.
- The write_host instruction writes the 512 KB of output activations, starting at u#524288, back to the host CPU.

We will progressively add realistic details to the pseudo-assembly language to explore some aspects of TPU design.

- a. [20] While we have written our pseudo-code in terms of bytes and byte addresses (or in the case of the accumulators, in terms of addresses to 32-bit values), the TPU operates on a natural vector length of 256. This means that the unified buffer is typically addressed at 256-byte boundaries, the accumulators are addressed in groups of 256 32-bit values (or at 1 KB boundaries), and weights are loaded in groups of 65,536 8-bit values. Rewrite the program’s addresses and transfer sizes to take these vector and weight-tile lengths into account. How many 256-element vectors of input activations will be read by the program? How many bytes of accumulated values will be used while computing the results? How many 256-element vectors of output activations will be written back to the host?

- b. [25] Suppose that the application requirements change, and instead of a multiplication by a 256×256 weight matrix, the shape of the weight matrix now becomes 1024×256 . Think of the `matmul` instruction as putting the weights as the right argument of the matrix multiplication operator, so 1024 corresponds to K, the dimension in which the matrix multiplication adds up values. Suppose that there are now two variants of the `accumulate` instruction, one of which overwrites the accumulators with its results, and the other of which adds the matrix multiplication results to the specified accumulator. How would you change the program to handle this 1024×256 matrix? Do you need more accumulators? The size of the matrix unit remains the same at 256×256 ; how many 256×256 weight tiles does your program need?
 - c. [25] Now write the program to handle a multiplication by a weight matrix of size 256×512 . Does your program need more accumulators? Can you rewrite your program so that it uses only 2048, 256-entry accumulators? How many weight tiles does your program need? In what order should they be stored in the weight DRAM?
 - d. [25] Next, write the program to handle a multiplication by a weight matrix of size 1024×768 . How many weight tiles does your program need? Write your program so that it uses only 2048, 256-entry accumulators. In what order should the weight tiles be stored in the weight DRAM? For this calculation, how many times did each input activation get read?
 - e. [Discussion] What would it take to build an architecture that reads each 256-element set of input activations just once? How many accumulators would that require? If you did it that way, how big would the accumulator memory have to be? Contrast this approach with the TPU, which uses 4096 accumulators, so that one set of 2048 accumulators can be written by the matrix unit while another is being used for activations.
- 7.4 [15/15/15] <7.3,7.4> Consider the first convolutional layer of AlexNet, which uses a 7×7 convolutional kernel, with an input feature depth of 3 and an output feature depth of 48. The original image width is 220×220 .
- a. [15] Ignore the 7×7 convolutional kernel for the moment, and consider just the center element of that kernel. A 1×1 convolutional kernel is mathematically equivalent to a matrix multiplication, using a weight matrix that is `input_depth` \times `output_depth` in dimensions. With these depths, and using a standard matrix multiplication, what fraction of the TPU's 65,536 ALUs can be used?
 - b. [15] For convolutional neural networks, the spatial dimensions are also sources of weight reuse, since the convolutional kernel gets applied to many different (x,y) coordinate positions. Suppose that the TPU reaches balanced compute and memory at a batch size of 1400 (as you might have computed in exercise 1d). What is the smallest square image size that the TPU can process efficiently at a batch size of 1?
 - c. [15] The first convolutional layer of AlexNet implements a *kernel stride* of 4, which means that rather than moving by one X or Y pixel at each application,

the 7×7 kernel moves by 4 pixels at a time. This striding means that we can permute the input data from $220 \times 220 \times 3$ to be $55 \times 55 \times 48$ (dividing the X and Y dimensions by 4 and multiplying the input depth by 16), and simultaneously we can restack the $7 \times 7 \times 3 \times 48$ convolutional weights to be $2 \times 2 \times 48 \times 48$ (just as the input data gets restacked by 4 in X and Y, we do the same to the 7×7 elements of the convolutional kernel, ending up with $\text{ceiling}(7/4)=2$ elements in each of the X and Y dimensions). Because the kernel is now 2×2 , we need to perform only four matrix multiplication operations, using weight matrices of size 48×48 . What is the fraction of the 65,536 ALUs that can be used now?

- 7.5 [15/10/20/20/20/25] < 7.3 > The TPU uses *fixed-point arithmetic* (sometimes also called *quantized arithmetic*, with overlapping and conflicting definitions), where integers are used to represent values on the real number line. There are a number of different schemes for fixed-point arithmetic, but they share the common theme that there is an affine projection from the integer used by hardware to the real number that the integer represents. An affine projection has the form $r = i*s + b$, where i is the integer, r is the represented real value, and s and b are a scale and bias. You can of course write the projection in either direction, from integers to reals or vice versa (although you need to round when converting from reals to integers).
- [15] The simplest activation function supported by the TPU is “ReLU6,” which is a rectified linear unit with a maximum of 6. For example, ReLU6 is defined by $\text{Relu6}(x) = \{ 0, \text{ when } x < 0; x, \text{ when } 0 \leq x \leq 6; \text{ and } 6, \text{ when } x > 6 \}$. So 0.0 and 6.0 on the real number line are the minimum and maximum values that Relu6 might produce. Assume that you use an 8-bit unsigned integer in hardware, and that you want to make 0 map to 0.0 and 255 map to 6.0. Solve for s and b .
 - [10] How many values on the real number line are exactly representable by an 8-bit quantized representation of ReLU6 output? What is the real-number spacing between them?
 - [20] The difference between representable values is sometimes called a “unit in the least place,” or *ulp*, when performing numerical analysis. If you map a real number to its fixed-point representation, then map back, you only rarely get back the original real number. The difference between the original number and its representation is called the *quantization error*. When mapping a real number in the range $[0.0, 6.0]$ to an 8-bit integer, show that the worst-case quantization error is one-half of an ulp (make sure you round to the nearest representable value). You might consider graphing the errors as a function of the original real number.
 - [20] Keep the real-number range $[0.0, 6.0]$ for an 8-bit integer from the last step. What 8-bit unsigned integer represents 1.0? What is the quantization error for 1.0? Suppose that you ask the TPU to add 1.0 to 1.0. What answer do you get back, and what is the error in that result?
 - [20] If you pick a random number uniformly in the range $[0.0, 6.0]$, then quantize it to an 8-bit unsigned integer, what distribution would you expect to see for the 256 integer values?

f. [25] The hyperbolic tangent function, \tanh , is another commonly used activation function in deep learning: $\tanh(x) = \frac{1 - e^{-2x}}{1 + e^{-2x}}$

Tanh also has a bounded range, mapping the entire real number line to the interval $(-1.0, 1.0)$. Solve for s and b for this range, using an 8-bit unsigned representation. Then solve for s and b using an 8-bit two's complement representation. For both cases, what real number does the integer 0 represent? Which integer represents the real number 0.0? Can you imagine any issues that might result from the quantization error incurred when representing 0.0?

- 7.6 [20/25/15/15/30/30/30/40/40/25/20/Discussion] <7.3> In addition to \tanh , another s-shaped smooth function, the logistic sigmoid function $y = 1 / (1 + \exp(-x))$,

$$\text{logistic_sigmoid}(x) = \frac{1}{1 + e^{-x}}$$

is commonly used as an activation function in neural networks. A common way to implement them in fixed-point arithmetic uses a piecewise quadratic approximation, where the most significant bits of the input value select which table entry to use. Then the least significant bits of the input value are sent to a degree-2 polynomial that describes a parabola that is fit to the subrange of the approximated function.

- a. [20] Using a graphing tool (we like www.desmos.com/calculator), draw the graphs for the logistic sigmoid and \tanh functions.
- b. [25] Now draw the graph of $y = \tanh(x/2)/2$. Compare that graph with the logistic sigmoid function. How much do they differ by? Build an equation that shows how to transform one into the other. Prove that your equation is correct.
- c. [15] Given this algebraic identity, do you need to use two different sets of coefficients to approximate logistic sigmoid and \tanh ?
- d. [15] Tanh is an odd function, meaning that $f(-x) = -f(x)$. Can you exploit this fact to save table space?
- e. [30] Let's focus our attention on approximating \tanh over the interval $x \in [0.0, 6.4]$ on the number line. Using floating-point arithmetic, write a program that divides the interval into 64 subintervals (each of length 0.1), and then approximates the value of \tanh over each subinterval using a single constant floating-point value (so you'll need to pick 64 different floating-point values, one for each subinterval). If you spot-check 100 different values (randomly chosen is fine) within each subinterval, what is the worst-case approximation error you see over all subintervals? Can you choose your constant to minimize the approximation error for each subinterval?
- f. [30] Now consider building a floating-point linear approximation for each subinterval. In this case, you want to pick a pair of floating-point values m and b , for the traditional line equation $y = mx + b$, to approximate each of the 64 subintervals. Come up with a strategy that you think is reasonable to build this linear interpolation over 64 subintervals for \tanh . Measure the worst-case approximation error over the 64 intervals. Is your approximation monotonic when it reaches a boundary between subintervals?

- g. [40] Next, build a quadratic approximation, using the standard formula $y = ax^2 + bx + c$. Experiment with a number of different ways to fit the formula. Try fitting the parabola to the endpoints and midpoint of the bucket, or using a Taylor approximation around a single point in the bucket. What worst-case error do you get?
- h. [40] (extra credit) Let's combine the numerical approximations of this exercise with the fixed-point arithmetic of the previous exercise. Suppose that the input $x \in [0.0, 6.4]$ is represented by a 15-bit unsigned value, with 0x0000 representing 0.0 and 0x7FFF representing 6.4. For the output, similarly use a 15-bit unsigned value, with 0x0000 representing 0.0 and 0x7FFF representing 1.0. For each of your constant, linear, and quadratic approximations, calculate the combined effect of approximation and quantization errors. Since there are so few input values, you can write a program to check them exhaustively.
- i. [25] For the quadratic, quantized approximation, is your approximation monotonic within each subinterval?
- j. [20] A difference of one ulp in the output scale should correspond to an error of $1.0 / 32767$. How many ulps of error are you seeing in each case?
- k. [Discussion] By choosing to approximate the interval $[0.0, 6.4]$, we effectively clipped the "tail" of the hyperbolic tangent function, for values of $x > 6.4$. It's not an unreasonable approximation to set the output value for all of the tail to 1.0. What's the worst-case error, in terms of both real numbers and ulps, of treating the tail this way? Is there a better place we might have clipped the tail to improve our accuracy?

Exercises

- 7.7 [10/20/10/15] <7.2,7.5> One popular family of FPGAs, the Virtex-7 series, is built by Xilinx. A Virtex-7 XC7VX690T FPGA contains 3,600 25x18-bit integer multiply-add "DSP slices." Consider building a TPU-style design on such an FPGA.
 - a. [10] Using one 25×18 integer multiplier per systolic array cell, what's the largest matrix multiplication unit one could construct? Assume that the matrix multiplication unit must be square.
 - b. [20] Suppose that you could build a rectangular, nonsquare matrix multiplication unit. What implications would such a design have for hardware and software? (Hint: think about the vector length that software must handle.)
 - c. [10] Many FPGA designs are lucky to reach 500 MHz operation. At that speed, calculate the peak 8-bit operations per second that such a device might achieve. How does that compare to the 3 T FLOPS of a K80 GPU?
 - d. [15] Assume that you can make up the difference between 3600 and 4096 DSP slices using LUTs, but that doing so will reduce your clock rate to 350 MHz. Is this a worthwhile trade-off to make?

- 7.8 [15/15/15] <7.9> Amazon Web Services (AWS) offers a wide variety of “computing instances,” which are machines configured to target different applications and scales. AWS prices tell us useful data about the Total Cost of Ownership (TCO) of various computing devices, particularly as computer equipment is often depreciated¹ on a 3-year schedule. As of July 2017, a dedicated, compute-oriented “c4” computing instance includes two x86 chips with 20 physical cores in total. It rents on-demand for \$1.75/hour, or \$17,962 for 3 years. In contrast, a dedicated “p2” computing instance also has two x86 chips but with 36 cores in total, and adds 16 NVIDIA K80 GPUs. A p2 rents on-demand for \$15.84/hour, or \$184,780 for 3 years.
- [15] The c4 instance uses Intel Xeon E5-2666 v3 (Haswell) processors. The p2 instance uses Intel Xeon E5-2686 v4 (Broadwell) processors. Neither part number is listed officially on Intel’s product website, which suggests that these parts are specially built for Amazon by Intel. The E5-2660 v3 part has a similar core count to the E5-2666 v3 and has a street price of around \$1500. The E5-2697 v4 part has a similar core count to the E5-2686 v4 and has a street price of around \$3000. Assume that the non-GPU portion of the p2 instance would have a price proportional to the ratio of street prices. What is the TCO, over 3 years, for a single K80 GPU?
 - [15] Suppose that you have a compute- and throughput-dominated workload that runs at rate 1 on the c4 instance and at rate T on the GPU-accelerated p2 instance. How large must T be for the GPU-based solution to be more cost-effective? Suppose that each general-purpose CPU core can compute at a rate of about 30G single-precision FLOPS. Ignoring the CPUs of the p2 instance, what fraction of peak K80 FLOPs would be required to reach the same rate of computation as the c4 instance?
 - [15] AWS also offers “f1” instances that include 8 Xilinx Ultrascale+ VU9P FPGAs. They rent at \$13.20/hour, or \$165,758 for 3 years. Each VU9P device includes 6840 DSP slices, which can perform 27×18 -bit integer multiply-accumulate operations (recall that one multiply-accumulate counts as two “operations”). At 500 MHz, what is the peak multiply-accumulate operations/cycle that an f1-based system might achieve, counting all 8 FPGAs toward the computation total? Assuming that the integer operations on the FPGAs can substitute for floating-point operations, how does this compare to the peak single-precision multiply-accumulate operations/cycle of the GPUs of the p2 instance? How do they compare in terms of cost-effectiveness?
- 7.9 [20/20/25] <7.7> As shown in Figure 7.34 (but simplified to fewer PEs), each Pixel Visual Core includes a 16×16 set of full processing elements, surrounded

¹Capital expenses are accounted for over the lifetime of an asset, using a “depreciation schedule.” Rather than taking a one-time charge at the point where an asset is acquired, standard accounting practice spreads out the capital cost over the lifetime of the asset. So one might account for a \$30,000 device that has a useful life of 3 years by assigning \$10,000 in depreciation to each year.

by an additional two layers of “simplified” processing elements. Simplified PEs can store and communicate data but omit the computation hardware of full PEs. Simplified PEs store copies of data that might be the “home data” of a neighboring core, so there are $(16+2+2)^2=400$ PEs in total, 256 full and 144 simplified.

- a. [20] Suppose that you wanted to process a 64×32 grayscale image with a 5×5 stencil using 8 Pixel Visual Cores. For now, assume that the image is laid out in raster-scan order (pixels that are adjacent in X are adjacent in memory, while pixels that are adjacent in Y are 64 memory locations apart). For each of the 8 cores, describe the memory region that the core should import to handle its part of the image. Make sure to include the halo region. Which parts of the halo region should be zeroed by software to ensure correct operation? You may find it convenient to refer to subregions of the image using a 2D slice notation, where for example `image[2:5][6:13]` refers to the set of pixels whose x component is $2 \leq x < 5$ and whose y component is $6 \leq y < 13$ (the slices are half-open following Python slicing practice).
- b. [20] If we change to a 3×3 stencil, how do the regions imported from memory change? How many halo-simplified PEs go unused?
- c. [25] Now consider how to support a 7×7 stencil. In this case, we don’t have as many hardware-supported simplified PEs as we need to cover the three pixels worth of halo data that “belong to” neighboring cores. To handle this, we use the outermost ring of full PEs as if they were simplified PEs. How many pixels can we handle in a single core using this strategy? How many “tiles” are now required to handle our 64×32 input image? What is the utilization of our full PEs over the complete processing time for the 7×7 stencil over the 64×32 image?

- 7.10 [20/20/20/25/25] <7.7> Consider a case in which each of the eight cores on a Pixel Visual Core device is connected through a four-port switch to a 2D SRAM, forming a core+memory unit. The remaining two ports on the switch link these units in a ring, so that each core is able to access any of the eight SRAMs. However, this ring-based network-on-chip topology makes some data access patterns more efficient than others.

- a. [20] Suppose that each link in the NOC has the same bandwidth B , and that each link is full-duplex, so it can simultaneously transfer bandwidth B in each direction. Links connect the core to the switch, the switch to SRAM, and pairs of switches in the ring. Assume that each local memory has at least B bandwidth, so it can saturate its link. Consider a memory access pattern where each of the eight PEs access only the closest memory (the one connected via the switch of the core+memory unit). What is the maximum memory bandwidth that the core will be able to achieve?
 - b. [20] Now consider an off-by-one access pattern, where core i accesses memory $i + 1$, going through three links to reach that memory (core 7 will access memory 0, because of the ring topology). What is the maximum memory bandwidth that the core will be able to achieve in this case? To achieve that bandwidth, do you need to make any assumptions about the capabilities of the 4-port switch? What if the switch can only move data at rate B ?
 - c. [20] Consider an off-by-two access pattern, where core i access memory $i + 2$. Once again, what is the maximum memory bandwidth that the core will be able to achieve in this case? Where are the bottleneck links in the network-on-chip?
 - d. [25] Consider a uniform random memory access pattern, where each core uses each of the SRAMs for $1/8$ of its memory requests. Assuming this traffic pattern, how much traffic traverses a switch-to-switch link, compared to the amount of traffic between a core and its associated switch or between an SRAM and its associated switch?
 - e. [25] (advanced) Can you conceive of a case (workload) where this network can deadlock? From the standpoint of software-only solutions, what should the compiler do to avoid such a scenario? If you can make changes to hardware, what changes in routing topology (and routing scheme) would guarantee no deadlocks?
- 7.11 <7.2> The first Anton molecular dynamics supercomputer typically simulated a box of water that was 64 \AA on a side. The computer itself might be approximated as a box with 1 m side length. A single simulation step represented 2.5 fs of simulation time, and took about 10 μs of wall-clock time. The physics models used in molecular dynamics act as if every particle in the system exerts a force on every other particle in the system on each (“outer”) time step, requiring what amounts to a global synchronization across the entire computer.
- a. Calculate the spatial expansion factor from simulation space to hardware in real space.
 - b. Calculate the temporal slowdown factor from simulated time to wall-clock time.
 - c. These two numbers come out surprisingly close. Is this just a coincidence, or is there some other limit that constrains them in some way? (Hint: the speed of light applies to both the simulated chemical system and the hardware that does the simulation.)

- d. Given these limits, what would it take to use a warehouse-scale supercomputer to perform molecular dynamics simulations at Anton rates? That is, what's the fastest simulation step time that might be achieved with a machine 10^2 or 10^3 m on a side? What about simulating on a world-spanning Cloud service?
- 7.12 <7.2> The Anton communication network is a 3D, $8 \times 8 \times 8$ torus, where each node in the system has six links to neighboring nodes. Latency for a packet to transit single link is about 50 ns. Ignore on-chip switching time between links for this exercise.
- What is the diameter (maximum number of hops between a pair of nodes) of the communication network? Given that diameter, what is the shortest latency required to broadcast a single value from one node of the machine to all 512 nodes of the machine?
 - Assuming that adding up two values takes zero time, what is the shortest latency to add up a sum over 512 values to a single node, where each value starts on a different node of the machine?
 - Once again assume that you want to perform the sum over 512 values, but you want each of the 512 nodes of the system to end up with a copy of the sum. Of course you could perform a global reduction followed by a broadcast. Can you do the combined operation in less time? This pattern is called an *all-reduce*. Compare the times of your all-reduce pattern to the time of a broadcast from a single node or a global sum to a single node. Compare the bandwidth used by the all-reduce pattern with the other patterns.

A.1

Introduction

In this appendix we concentrate on instruction set architecture—the portion of the computer visible to the programmer or compiler writer. Most of this material should be review for readers of this book; we include it here for background. This appendix introduces the wide variety of design alternatives available to the instruction set architect. In particular, we focus on four topics. First, we present a taxonomy of instruction set alternatives and give some qualitative assessment of the advantages and disadvantages of various approaches. Second, we present and analyze some instruction set measurements that are largely independent of a specific instruction set. Third, we address the issue of languages and compilers and their bearing on instruction set architecture. Finally, the “Putting It All Together” section shows how these ideas are reflected in the RISC-V instruction set, which is typical of RISC architectures. We conclude with fallacies and pitfalls of instruction set design.

To illustrate the principles further and to provide a comparison with RISC-V, Appendix K also gives four examples of other general-purpose RISC architectures (MIPS, Power ISA, SPARC, and Armv8), four embedded RISC processors (ARM Thumb2, RISC-V Compressed, microMIPS), and three older architectures (80x86, IBM 360/370, and VAX). Before we discuss how to classify architectures, we need to say something about instruction set measurement.

Throughout this appendix, we examine a wide variety of architectural measurements. Clearly, these measurements depend on the programs measured and on the compilers used in making the measurements. The results should not be interpreted as absolute, and you might see different data if you did the measurement with a different compiler or a different set of programs. We believe that the measurements in this appendix are reasonably indicative of a class of typical applications. Many of the measurements are presented using a small set of benchmarks, so that the data can be reasonably displayed and the differences among programs can be seen. An architect for a new computer would want to analyze a much larger collection of programs before making architectural decisions. The measurements shown are usually *dynamic*—that is, the frequency of a measured event is weighed by the number of times that event occurs during execution of the measured program.

Before starting with the general principles, let’s review the three application areas from [Chapter 1](#). *Desktop computing* emphasizes the performance of programs with integer and floating-point data types, with little regard for program size. For example, code size has never been reported in the five generations of SPEC benchmarks. *Servers* today are used primarily for database, file server, and Web applications, plus some time-sharing applications for many users. Hence, floating-point performance is much less important for performance than integers and character strings, yet virtually every server processor still includes floating-point instructions. *Personal mobile devices* and *embedded applications* value cost and energy, so code size is important because less memory is both cheaper and lower energy, and some classes of instructions (such as floating point) may be optional to reduce chip costs, and a compressed version of the instructions set designed to save memory space may be used.

Thus, instruction sets for all three applications are very similar. In fact, architectures similar to RISC-V, which we focus on here, have been used successfully in desktops, servers, and embedded applications.

One successful architecture very different from RISC is the 80x86 (see Appendix K). Surprisingly, its success does not necessarily belie the advantages of a RISC instruction set. The commercial importance of binary compatibility with PC software combined with the abundance of transistors provided by Moore's Law led Intel to use a RISC instruction set internally while supporting an 80x86 instruction set externally. Recent 80x86 microprocessors, including all the Intel Core microprocessors built in the past decade, use hardware to translate from 80x86 instructions to RISC-like instructions and then execute the translated operations inside the chip. They maintain the illusion of 80x86 architecture to the programmer while allowing the computer designer to implement a RISC-style processor for performance. There remain, however, serious disadvantages for a complex instruction set like the 80x86, and we discuss these further in the conclusions.

Now that the background is set, we begin by exploring how instruction set architectures can be classified.

A.2

Classifying Instruction Set Architectures

The type of internal storage in a processor is the most basic differentiation, so in this section we will focus on the alternatives for this portion of the architecture. The major choices are a stack, an accumulator, or a set of registers. Operands may be named explicitly or implicitly: The operands in a *stack architecture* are implicitly on the top of the stack, and in an *accumulator architecture* one operand is implicitly the accumulator. The *general-purpose register architectures* have only explicit operands—either registers or memory locations. Figure A.1 shows a block diagram of such architectures, and Figure A.2 shows how the code sequence $C = A + B$ would typically appear in these three classes of instruction sets. The explicit operands may be accessed directly from memory or may need to be first loaded into temporary storage, depending on the class of architecture and choice of specific instruction.

As the figures show, there are really two classes of register computers. One class can access memory as part of any instruction, called *register-memory* architecture, and the other can access memory only with load and store instructions, called *load-store* architecture. A third class, not found in computers shipping today, keeps all operands in memory and is called a *memory-memory* architecture. Some instruction set architectures have more registers than a single accumulator but place restrictions on uses of these special registers. Such an architecture is sometimes called an *extended accumulator* or *special-purpose register* computer.

Although most early computers used stack or accumulator-style architectures, virtually every new architecture designed after 1980 uses a load-store register architecture. The major reasons for the emergence of general-purpose register (GPR) computers are twofold. First, registers—like other forms of storage internal to the processor—are faster than memory. Second, registers are more efficient for a

Figure A.1 Operand locations for four instruction set architecture classes. The arrows indicate whether the operand is an input or the result of the arithmetic-logical unit (ALU) operation, or both an input and result. Lighter shades indicate inputs, and the dark shade indicates the result. In (A), a top of stack (TOS) register points to the top input operand, which is combined with the operand below. The first operand is removed from the stack, the result takes the place of the second operand, and TOS is updated to point to the result. All operands are implicit. In (B), the accumulator is both an implicit input operand and a result. In (C), one input operand is a register, one is in memory, and the result goes to a register. All operands are registers in (D) and, like the stack architecture, can be transferred to memory only via separate instructions: push or pop for (A) and load or store for (D).

Stack	Accumulator	Register (register-memory)	Register (load-store)
Push A	Load A	Load R1,A	Load R1,A
Push B	Add B	Add R3,R1,B	Load R2,B
Add	Store C	Store R3,C	Add R3,R1,R2
Pop C			Store R3,C

Figure A.2 The code sequence for $C = A + B$ for four classes of instruction sets. Note that the Add instruction has implicit operands for stack and accumulator architectures and explicit operands for register architectures. It is assumed that A, B, and C all belong in memory and that the values of A and B cannot be destroyed. Figure A.1 shows the Add operation for each class of architecture.

compiler to use than other forms of internal storage. For example, on a register computer the expression $(A * B) + (B * C) - (A * D)$ may be evaluated by doing the multiplications in any order, which may be more efficient because of the location of the operands or because of pipelining concerns (see [Chapter 3](#)). Nevertheless, on a stack computer the hardware must evaluate the expression in only one order, because operands are hidden on the stack, and it may have to load an operand multiple times.

More importantly, registers can be used to hold variables. When variables are allocated to registers, the memory traffic reduces, the program speeds up (because registers are faster than memory), and the code density improves (because a register can be named with fewer bits than can a memory location).

As explained in [Section A.8](#), compiler writers would prefer that all registers be equivalent and unreserved. Older computers compromise this desire by dedicating registers to special uses, effectively decreasing the number of general-purpose registers. If the number of truly general-purpose registers is too small, trying to allocate variables to registers will not be profitable. Instead, the compiler will reserve all the uncommitted registers for use in expression evaluation.

How many registers are sufficient? The answer, of course, depends on the effectiveness of the compiler. Most compilers reserve some registers for expression evaluation, use some for parameter passing, and allow the remainder to be allocated to hold variables. Modern compiler technology and its ability to effectively use larger numbers of registers has led to an increase in register counts in more recent architectures.

Two major instruction set characteristics divide GPR architectures. Both characteristics concern the nature of operands for a typical arithmetic or logical instruction (ALU instruction). The first concerns whether an ALU instruction has two or three operands. In the three-operand format, the instruction contains one result operand and two source operands. In the two-operand format, one of the operands is both a source and a result for the operation. The second distinction among GPR architectures concerns how many of the operands may be memory addresses in ALU instructions. The number of memory operands supported by a typical ALU instruction may vary from none to three. [Figure A.3](#) shows combinations of these two attributes with examples of computers. Although there are seven

Number of memory addresses	Maximum number of operands allowed	Type of architecture	Examples
0	3	Load-store	ARM, MIPS, PowerPC, SPARC, RISC-V
1	2	Register-memory	IBM 360/370, Intel 80x86, Motorola 68000, TI TMS320C54x
2	2	Memory-memory	VAX (also has three-operand formats)
3	3	Memory-memory	VAX (also has two-operand formats)

Figure A.3 Typical combinations of memory operands and total operands per typical ALU instruction with examples of computers. Computers with no memory reference per ALU instruction are called load-store or register-register computers. Instructions with multiple memory operands per typical ALU instruction are called register-memory or memory-memory, according to whether they have one or more than one memory operand.

Type	Advantages	Disadvantages
Register-register (0, 3)	Simple, fixed-length instruction encoding. Simple code generation model. Instructions take similar numbers of clocks to execute (see Appendix C)	Higher instruction count than architectures with memory references in instructions. More instructions and lower instruction density lead to larger programs, which may have some instruction cache effects
Register-memory (1, 2)	Data can be accessed without a separate load instruction first. Instruction format tends to be easy to encode and yields good density	Operands are not equivalent because a source operand in a binary operation is destroyed. Encoding a register number and a memory address in each instruction may restrict the number of registers. Clocks per instruction vary by operand location
Memory-memory (2, 2) or (3, 3)	Most compact. Doesn't waste registers for temporaries	Large variation in instruction size, especially for three-operand instructions. In addition, large variation in work per instruction. Memory accesses create memory bottleneck. (Not used today.)

Figure A.4 Advantages and disadvantages of the three most common types of general-purpose register computers. The notation (m, n) means m memory operands and n total operands. In general, computers with fewer alternatives simplify the compiler's task because there are fewer decisions for the compiler to make (see [Section A.8](#)). Computers with a wide variety of flexible instruction formats reduce the number of bits required to encode the program. The number of registers also affects the instruction size because you need \log_2 (number of registers) for each register specifier in an instruction. Thus, doubling the number of registers takes three extra bits for a register-register architecture, or about 10% of a 32-bit instruction.

possible combinations, three serve to classify nearly all existing computers. As we mentioned earlier, these three are load-store (also called register-register), register-memory, and memory-memory.

[Figure A.4](#) shows the advantages and disadvantages of each of these alternatives. Of course, these advantages and disadvantages are not absolutes: they are qualitative and their actual impact depends on the compiler and implementation strategy. A GPR computer with memory-memory operations could easily be ignored by the compiler and used as a load-store computer. One of the most pervasive architectural impacts is on instruction encoding and the number of instructions needed to perform a task. We see the impact of these architectural alternatives on implementation approaches in [Appendix C](#) and [Chapter 3](#).

Summary: Classifying Instruction Set Architectures

Here and at the end of [Sections A.3–A.8](#) we summarize those characteristics we would expect to find in a new instruction set architecture, building the foundation for the RISC-V architecture introduced in [Section A.9](#). From this section we should clearly expect the use of general-purpose registers. [Figure A.4](#), combined with [Appendix C](#) on pipelining, leads to the expectation of a load-store version of a general-purpose register architecture.

With the class of architecture covered, the next topic is addressing operands.

A.3

Memory Addressing

Independent of whether the architecture is load-store or allows any operand to be a memory reference, it must define how memory addresses are interpreted and how they are specified. The measurements presented here are largely, but not completely, computer independent. In some cases the measurements are significantly affected by the compiler technology. These measurements have been made using an optimizing compiler, because compiler technology plays a critical role.

Interpreting Memory Addresses

How is a memory address interpreted? That is, what object is accessed as a function of the address and the length? All the instruction sets discussed in this book are byte addressed and provide access for bytes (8 bits), half words (16 bits), and words (32 bits). Most of the computers also provide access for double words (64 bits).

There are two different conventions for ordering the bytes within a larger object. *Little Endian* byte order puts the byte whose address is “x ... x000” at the least-significant position in the double word (the little end). The bytes are numbered:

7	6	5	4	3	2	1	0
---	---	---	---	---	---	---	---

Big Endian byte order puts the byte whose address is “x ... x000” at the most-significant position in the double word (the big end). The bytes are numbered:

0	1	2	3	4	5	6	7
---	---	---	---	---	---	---	---

When operating within one computer, the byte order is often unnoticeable—only programs that access the same locations as both, say, words and bytes, can notice the difference. Byte order is a problem when exchanging data among computers with different orderings, however. Little Endian ordering also fails to match the normal ordering of words when strings are compared. Strings appear “SDRAWKCAB” (backwards) in the registers.

A second memory issue is that in many computers, accesses to objects larger than a byte must be *aligned*. An access to an object of size s bytes at byte address A is aligned if $A \bmod s = 0$. [Figure A.5](#) shows the addresses at which an access is aligned or misaligned.

Why would someone design a computer with alignment restrictions? Misalignment causes hardware complications, because the memory is typically aligned on a multiple of a word or double-word boundary. A misaligned memory access may, therefore, take multiple aligned memory references. Thus, even in computers that allow misaligned access, programs with aligned accesses run faster.

Value of three low-order bits of byte address								
Width of object	0	1	2	3	4	5	6	7
1 byte (byte)	Aligned	Aligned	Aligned	Aligned	Aligned	Aligned	Aligned	Aligned
2 bytes (half word)	Aligned		Aligned		Aligned		Aligned	
2 bytes (half word)		Misaligned		Misaligned		Misaligned		Misaligned
4 bytes (word)	Aligned				Aligned			
4 bytes (word)		Misaligned				Misaligned		
4 bytes (word)		Misaligned					Misaligned	
4 bytes (word)					Misaligned			Misaligned
8 bytes (double word)	Aligned							
8 bytes (double word)		Misaligned						
8 bytes (double word)		Misaligned						
8 bytes (double word)					Misaligned			
8 bytes (double word)						Misaligned		
8 bytes (double word)							Misaligned	
8 bytes (double word)								Misaligned

Figure A.5 Aligned and misaligned addresses of byte, half-word, word, and double-word objects for byte-addressed computers. For each misaligned example some objects require two memory accesses to complete. Every aligned object can always complete in one memory access, as long as the memory is as wide as the object. The figure shows the memory organized as 8 bytes wide. The byte offsets that label the columns specify the low-order three bits of the address.

Even if data are aligned, supporting byte, half-word, and word accesses requires an alignment network to align bytes, half words, and words in 64-bit registers. For example, in [Figure A.5](#), suppose we read a byte from an address with its 3 low-order bits having the value 4. We will need to shift right 3 bytes to align the byte to the proper place in a 64-bit register. Depending on the instruction, the computer may also need to sign-extend the quantity. Stores are easy: only the addressed bytes in memory may be altered. On some computers a byte, half-word, and word operation does not affect the upper portion of a register. Although all the computers discussed in this book permit byte, half-word, and word accesses to memory, only the IBM 360/370, Intel 80x86, and VAX support ALU operations on register operands narrower than the full width.

Now that we have discussed alternative interpretations of memory addresses, we can discuss the ways addresses are specified by instructions, called *addressing modes*.

Addressing Modes

Given an address, we now know what bytes to access in memory. In this subsection we will look at addressing modes—how architectures specify the address

of an object they will access. Addressing modes specify constants and registers in addition to locations in memory. When a memory location is used, the actual memory address specified by the addressing mode is called the *effective address*.

Figure A.6 shows all the data addressing modes that have been used in recent computers. Immediates or literals are usually considered memory addressing modes (even though the value they access is in the instruction stream), although registers are often separated because they don't usually have memory addresses. We have kept addressing modes that depend on the program counter, called *PC-relative addressing*, separate. PC-relative addressing is used primarily for specifying code addresses in control transfer instructions, discussed in Section A.6.

Addressing mode	Example instruction	Meaning	When used
Register	Add R4, R3	$\text{Regs}[\text{R4}] \leftarrow \text{Regs}[\text{R4}] + \text{Regs}[\text{R3}]$	When a value is in a register
Immediate	Add R4, 3	$\text{Regs}[\text{R4}] \leftarrow \text{Regs}[\text{R4}] + 3$	For constants
Displacement	Add R4, 100(R1)	$\text{Regs}[\text{R4}] \leftarrow \text{Regs}[\text{R4}] + \text{Mem}[100 + \text{Regs}[\text{R1}]]$	Accessing local variables (+ simulates register indirect, direct addressing modes)
Register indirect	Add R4, (R1)	$\text{Regs}[\text{R4}] \leftarrow \text{Regs}[\text{R4}] + \text{Mem}[\text{Regs}[\text{R1}]]$	Accessing using a pointer or a computed address
Indexed	Add R3, (R1 + R2)	$\text{Regs}[\text{R3}] \leftarrow \text{Regs}[\text{R3}] + \text{Mem}[\text{Regs}[\text{R1}] + \text{Regs}[\text{R2}]]$	Sometimes useful in array addressing: R1 = base of array; R2 = index amount
Direct or absolute	Add R1, (1001)	$\text{Regs}[\text{R1}] \leftarrow \text{Regs}[\text{R1}] + \text{Mem}[1001]$	Sometimes useful for accessing static data; address constant may need to be large
Memory indirect	Add R1, @(R3)	$\text{Regs}[\text{R1}] \leftarrow \text{Regs}[\text{R1}] + \text{Mem}[\text{Mem}[\text{Regs}[\text{R3}]]]$	If R3 is the address of a pointer p , then mode yields $*p$
Autoincrement	Add R1, (R2) +	$\begin{aligned} \text{Regs}[\text{R1}] &\leftarrow \text{Regs}[\text{R1}] + \text{Mem}[\text{Regs}[\text{R2}]] \\ \text{Regs}[\text{R2}] &\leftarrow \text{Regs}[\text{R2}] + d \end{aligned}$	Useful for stepping through arrays within a loop. R2 points to start of array; each reference increments R2 by size of an element, d
Autodecrement	Add R1, -(R2)	$\begin{aligned} \text{Regs}[\text{R2}] &\leftarrow \text{Regs}[\text{R2}] - d \\ \text{Regs}[\text{R1}] &\leftarrow \text{Regs}[\text{R1}] + \text{Mem}[\text{Regs}[\text{R2}]] \end{aligned}$	Same use as autoincrement. Autodecrement/-increment can also act as push/pop to implement a stack.
Scaled	Add R1, 100(R2)[R3]	$\text{Regs}[\text{R1}] \leftarrow \text{Regs}[\text{R1}] + \text{Mem}[100 + \text{Regs}[\text{R2}] + \text{Regs}[\text{R3}] * d]$	Used to index arrays. May be applied to any indexed addressing mode in some computers

Figure A.6 Selection of addressing modes with examples, meaning, and usage. In autoincrement/-decrement and scaled addressing modes, the variable d designates the size of the data item being accessed (i.e., whether the instruction is accessing 1, 2, 4, or 8 bytes). These addressing modes are only useful when the elements being accessed are adjacent in memory. RISC computers use displacement addressing to simulate register indirect with 0 for the address and to simulate direct addressing using 0 in the base register. In our measurements, we use the first name shown for each mode. The extensions to C used as hardware descriptions are defined on page A.38.

Figure A.6 shows the most common names for the addressing modes, though the names differ among architectures. In this figure and throughout the book, we will use an extension of the C programming language as a hardware description notation. In this figure, only one non-C feature is used: the left arrow (\leftarrow) is used for assignment. We also use the array `Mem` as the name for main memory and the array `Regs` for registers. Thus, `Mem[Regs[R1]]` refers to the contents of the memory location whose address is given by the contents of register 1 (`R1`). Later, we will introduce extensions for accessing and transferring data smaller than a word.

Addressing modes have the ability to significantly reduce instruction counts; they also add to the complexity of building a computer and may increase the average clock cycles per instruction (CPI) of computers that implement those modes. Thus, the usage of various addressing modes is quite important in helping the architect choose what to include.

Figure A.7 shows the results of measuring addressing mode usage patterns in three programs on the VAX architecture. We use the old VAX architecture for a few measurements in this appendix because it has the richest set of addressing

Figure A.7 Summary of use of memory addressing modes (including immediates). These major addressing modes account for all but a few percent (0%–3%) of the memory accesses. Register modes, which are not counted, account for one-half of the operand references, while memory addressing modes (including immediate) account for the other half. Of course, the compiler affects what addressing modes are used; see [Section A.8](#). The memory indirect mode on the VAX can use displacement, autoincrement, or autodecrement to form the initial memory address; in these programs, almost all the memory indirect references use displacement mode as the base. Displacement mode includes all displacement lengths (8, 16, and 32 bits). The PC-relative addressing modes, used almost exclusively for branches, are not included. Only the addressing modes with an average frequency of over 1% are shown.

modes and the fewest restrictions on memory addressing. For example, [Figure A.6](#) on page A.9 shows all the modes the VAX supports. Most measurements in this appendix, however, will use the more recent register-register architectures to show how programs use instruction sets of current computers.

As [Figure A.7](#) shows, displacement and immediate addressing dominate addressing mode usage. Let's look at some properties of these two heavily used modes.

Displacement Addressing Mode

The major question that arises for a displacement-style addressing mode is that of the range of displacements used. Based on the use of various displacement sizes, a decision of what sizes to support can be made. Choosing the displacement field sizes is important because they directly affect the instruction length. [Figure A.8](#)

Figure A.8 Displacement values are widely distributed. There are both a large number of small values and a fair number of large values. The wide distribution of displacement values is due to multiple storage areas for variables and different displacements to access them (see [Section A.8](#)) as well as the overall addressing scheme the compiler uses. The x-axis is \log_2 of the displacement, that is, the size of a field needed to represent the magnitude of the displacement. Zero on the x-axis shows the percentage of displacements of value 0. The graph does not include the sign bit, which is heavily affected by the storage layout. Most displacements are positive, but a majority of the largest displacements (14+ bits) are negative. Because these data were collected on a computer with 16-bit displacements, they cannot tell us about longer displacements. These data were taken on the Alpha architecture with full optimization (see [Section A.8](#)) for SPEC CPU2000, showing the average of integer programs (CINT2000) and the average of floating-point programs (CFP2000).

shows the measurements taken on the data access on a load-store architecture using our benchmark programs. We look at branch offsets in [Section A.6](#)—data accessing patterns and branches are different; little is gained by combining them, although in practice the immediate sizes are made the same for simplicity.

Immediate or Literal Addressing Mode

Immediates can be used in arithmetic operations, in comparisons (primarily for branches), and in moves where a constant is wanted in a register. The last case occurs for constants written in the code—which tend to be small—and for address constants, which tend to be large. For the use of immediates it is important to know whether they need to be supported for all operations or for only a subset. [Figure A.9](#) shows the frequency of immediates for the general classes of integer and floating-point operations in an instruction set.

Another important instruction set measurement is the range of values for immediates. Like displacement values, the size of immediate values affects instruction length. As [Figure A.10](#) shows, small immediate values are most heavily used. Large immediates are sometimes used, however, most likely in addressing calculations.

Summary: Memory Addressing

First, because of their popularity, we would expect a new architecture to support at least the following addressing modes: displacement, immediate, and register indirect. [Figure A.7](#) shows that they represent 75%–99% of the addressing modes used

Figure A.9 About one-quarter of data transfers and ALU operations have an immediate operand. The bottom bars show that integer programs use immediates in about one-fifth of the instructions, while floating-point programs use immediates in about one-sixth of the instructions. For loads, the load immediate instruction loads 16 bits into either half of a 32-bit register. Load immediates are not loads in a strict sense because they do not access memory. Occasionally a pair of load immediates is used to load a 32-bit constant, but this is rare. (For ALU operations, shifts by a constant amount are included as operations with immediate operands.) The programs and computer used to collect these statistics are the same as in [Figure A.8](#).

Figure A.10 The distribution of immediate values. The x-axis shows the number of bits needed to represent the magnitude of an immediate value—0 means the immediate field value was 0. The majority of the immediate values are positive. About 20% were negative for CINT2000, and about 30% were negative for CFP2000. These measurements were taken on an Alpha, where the maximum immediate is 16 bits, for the same programs as in Figure A.8. A similar measurement on the VAX, which supported 32-bit immediates, showed that about 20%–25% of immediates were longer than 16 bits. Thus, 16 bits would capture about 80% and 8 bits about 50%.

in our measurements. Second, we would expect the size of the address for displacement mode to be at least 12–16 bits, because the caption in Figure A.8 suggests these sizes would capture 75%–99% of the displacements. Third, we would expect the size of the immediate field to be at least 8–16 bits. This claim is not substantiated by the caption of the figure to which it refers.

Having covered instruction set classes and decided on register-register architectures, plus the previous recommendations on data addressing modes, we next cover the sizes and meanings of data.

A.4

Type and Size of Operands

How is the type of an operand designated? Usually, encoding in the opcode designates the type of an operand—this is the method used most often. Alternatively, the data can be annotated with tags that are interpreted by the hardware. These tags specify the type of the operand, and the operation is chosen accordingly. Computers with tagged data, however, can only be found in computer museums.

Let's start with desktop and server architectures. Usually the type of an operand—integer, single-precision floating point, character, and so on—effectively

gives its size. Common operand types include character (8 bits), half word (16 bits), word (32 bits), single-precision floating point (also 1 word), and double-precision floating point (2 words). Integers are almost universally represented as two's complement binary numbers. Characters are usually in ASCII, but the 16-bit Unicode (used in Java) is gaining popularity with the internationalization of computers. Until the early 1980s, most computer manufacturers chose their own floating-point representation. Almost all computers since that time follow the same standard for floating point, the IEEE standard 754, although this level of accuracy has recently been abandoned in application-specific processors. The IEEE floating-point standard is discussed in detail in Appendix J.

Some architectures provide operations on character strings, although such operations are usually quite limited and treat each byte in the string as a single character. Typical operations supported on character strings are comparisons and moves.

For business applications, some architectures support a decimal format, usually called *packed decimal* or *binary-coded decimal*—4 bits are used to encode the values 0–9, and 2 decimal digits are packed into each byte. Numeric character strings are sometimes called *unpacked decimal*, and operations—called *packing* and *unpacking*—are usually provided for converting back and forth between them.

One reason to use decimal operands is to get results that exactly match decimal numbers, as some decimal fractions do not have an exact representation in binary. For example, 0.10_{10} is a simple fraction in decimal, but in binary it requires an infinite set of repeating digits: $0.0001100110011\dots_2$. Thus, calculations that are exact in decimal can be close but inexact in binary, which can be a problem for financial transactions. (See Appendix J to learn more about precise arithmetic.)

The SPEC benchmarks use byte or character, half-word (short integer), word (integer and single precision floating point), double-word (long integer), and floating-point data types. Figure A.11 shows the dynamic distribution of the sizes of objects referenced from memory for these programs. The frequency of access to

Figure A.11 Distribution of data accesses by size for the benchmark programs. The double-word data type is used for double-precision floating point in floating-point programs and for addresses, because the computer uses 64-bit addresses. On a 32-bit address computer the 64-bit addresses would be replaced by 32-bit addresses, and so almost all double-word accesses in integer programs would become single-word accesses.

different data types helps in deciding what types are most important to support efficiently. Should the computer have a 64-bit access path, or would taking two cycles to access a double word be satisfactory? As we saw earlier, byte accesses require an alignment network: how important is it to support bytes as primitives? [Figure A.11](#) uses memory references to examine the types of data being accessed.

In some architectures, objects in registers may be accessed as bytes or half words. However, such access is very infrequent—on the VAX, it accounts for no more than 12% of register references, or roughly 6% of all operand accesses in these programs.

A.5

Operations in the Instruction Set

The operators supported by most instruction set architectures can be categorized as in [Figure A.12](#). One rule of thumb across all architectures is that the most widely executed instructions are the simple operations of an instruction set. For example, [Figure A.13](#) shows 10 simple instructions that account for 96% of instructions executed for a collection of integer programs running on the popular Intel 80x86. Hence, the implementor of these instructions should be sure to make these fast, as they are the common case.

Operator type	Examples
Arithmetic and logical	Integer arithmetic and logical operations: add, subtract, and, or, multiply, divide
Data transfer	Loads-stores (move instructions on computers with memory addressing)
Control	Branch, jump, procedure call and return, traps
System	Operating system call, virtual memory management instructions
Floating point	Floating-point operations: add, multiply, divide, compare
Decimal	Decimal add, decimal multiply, decimal-to-character conversions
String	String move, string compare, string search
Graphics	Pixel and vertex operations, compression/decompression operations

Figure A.12 Categories of instruction operators and examples of each. All computers generally provide a full set of operations for the first three categories. The support for system functions in the instruction set varies widely among architectures, but all computers must have some instruction support for basic system functions. The amount of support in the instruction set for the last four categories may vary from none to an extensive set of special instructions. Floating-point instructions will be provided in any computer that is intended for use in an application that makes much use of floating point. These instructions are sometimes part of an optional instruction set. Decimal and string instructions are sometimes primitives, as in the VAX or the IBM 360, or may be synthesized by the compiler from simpler instructions. Graphics instructions typically operate on many smaller data items in parallel—for example, performing eight 8-bit additions on two 64-bit operands.

Rank	80x86 instruction	Integer average % total executed)
1	Load	22%
2	Conditional branch	20%
3	Compare	16%
4	Store	12%
5	Add	8%
6	And	6%
7	Sub	5%
8	Move register-register	4%
9	Call	1%
10	Return	1%
Total		96%

Figure A.13 The top 10 instructions for the 80x86. Simple instructions dominate this list and are responsible for 96% of the instructions executed. These percentages are the average of the five SPECint92 programs.

As mentioned before, the instructions in [Figure A.13](#) are found in every computer for every application—desktop, server, embedded—with the variations of operations in [Figure A.12](#) largely depending on which data types the instruction set includes.

A.6

Instructions for Control Flow

Because the measurements of branch and jump behavior are fairly independent of other measurements and applications, we now examine the use of control flow instructions, which have little in common with the operations of the previous sections.

There is no consistent terminology for instructions that change the flow of control. In the 1950s they were typically called *transfers*. Beginning in 1960 the name *branch* began to be used. Later, computers introduced additional names. Throughout this book we will use *jump* when the change in control is unconditional and *branch* when the change is conditional.

We can distinguish four different types of control flow change:

- Conditional branches
- Jumps
- Procedure calls
- Procedure returns

We want to know the relative frequency of these events, as each event is different, may use different instructions, and may have different behavior. [Figure A.14](#) shows the frequencies of these control flow instructions for a load-store computer running our benchmarks.

Figure A.14 Breakdown of control flow instructions into three classes: calls or returns, jumps, and conditional branches. Conditional branches clearly dominate. Each type is counted in one of three bars. The programs and computer used to collect these statistics are the same as those in [Figure A.8](#).

Addressing Modes for Control Flow Instructions

The destination address of a control flow instruction must always be specified. This destination is specified explicitly in the instruction in the vast majority of cases—procedure return being the major exception, because for return the target is not known at compile time. The most common way to specify the destination is to supply a displacement that is added to the *program counter* (PC). Control flow instructions of this sort are called *PC-relative*. PC-relative branches or jumps are advantageous because the target is often near the current instruction, and specifying the position relative to the current PC requires fewer bits. Using PC-relative addressing also permits the code to run independently of where it is loaded. This property, called *position independence*, can eliminate some work when the program is linked and is also useful in programs linked dynamically during execution.

To implement returns and indirect jumps when the target is not known at compile time, a method other than PC-relative addressing is required. Here, there must be a way to specify the target dynamically, so that it can change at runtime. This dynamic address may be as simple as naming a register that contains the target address; alternatively, the jump may permit any addressing mode to be used to supply the target address.

These register indirect jumps are also useful for four other important features:

- *Case* or *switch* statements, found in most programming languages (which select among one of several alternatives).
- *Virtual functions* or *methods* in object-oriented languages like C++ or Java (which allow different routines to be called depending on the type of the argument).

- *High-order functions* or *function pointers* in languages like C or C++ (which allow functions to be passed as arguments, giving some of the flavor of object-oriented programming).
- *Dynamically shared libraries* (which allow a library to be loaded and linked at runtime only when it is actually invoked by the program rather than loaded and linked statically before the program is run).

In all four cases the target address is not known at compile time, and hence is usually loaded from memory into a register before the register indirect jump.

As branches generally use PC-relative addressing to specify their targets, an important question concerns how far branch targets are from branches. Knowing the distribution of these displacements will help in choosing what branch offsets to support, and thus will affect the instruction length and encoding. [Figure A.15](#) shows the distribution of displacements for PC-relative branches in instructions. About 75% of the branches are in the forward direction.

Conditional Branch Options

Because most changes in control flow are branches, deciding how to specify the branch condition is important. [Figure A.16](#) shows the three primary techniques in use today and their advantages and disadvantages.

Figure A.15 Branch distances in terms of number of instructions between the target and the branch instruction.

The most frequent branches in the integer programs are to targets that can be encoded in 4–8 bits. This result tells us that short displacement fields often suffice for branches and that the designer can gain some encoding density by having a shorter instruction with a smaller branch displacement. These measurements were taken on a load-store computer (Alpha architecture) with all instructions aligned on word boundaries. An architecture that requires fewer instructions for the same program, such as a VAX, would have shorter branch distances. However, the number of bits needed for the displacement may increase if the computer has variable-length instructions to be aligned on any byte boundary. The programs and computer used to collect these statistics are the same as those in [Figure A.8](#).

Name	Examples	How condition is tested	Advantages	Disadvantages
Condition code (CC)	80x86, ARM, PowerPC, SPARC, SuperH	Tests special bits set by ALU operations, possibly under program control	Sometimes condition is set for free.	CC is extra state. Condition codes constrain the ordering of instructions because they pass information from one instruction to a branch
Condition register/limited comparison	Alpha, MIPS	Tests arbitrary register with the result of a simple comparison (equality or zero tests)	Simple	Limited compare may affect critical path or require extra comparison for general condition
Compare and branch	PA-RISC, VAX, RISC-V	Compare is part of the branch. Fairly general compares are allowed (greater than, less than)	One instruction rather than two for a branch	May set critical path for branch instructions

Figure A.16 The major methods for evaluating branch conditions, their advantages, and their disadvantages. Although condition codes can be set by ALU operations that are needed for other purposes, measurements on programs show that this rarely happens. The major implementation problems with condition codes arise when the condition code is set by a large or haphazardly chosen subset of the instructions, rather than being controlled by a bit in the instruction. Computers with compare and branch often limit the set of compares and use a separate operation and register for more complex compares. Often, different techniques are used for branches based on floating-point comparison versus those based on integer comparison. This dichotomy is reasonable because the number of branches that depend on floating-point comparisons is much smaller than the number depending on integer comparisons.

One of the most noticeable properties of branches is that a large number of the comparisons are simple tests, and a large number are comparisons with zero. Thus, some architectures choose to treat these comparisons as special cases, especially if a *compare and branch* instruction is being used. [Figure A.17](#) shows the frequency of different comparisons used for conditional branching.

Procedure Invocation Options

Procedure calls and returns include control transfer and possibly some state saving; at a minimum the return address must be saved somewhere, sometimes in a special link register or just a GPR. Some older architectures provide a mechanism to save many registers, while newer architectures require the compiler to generate stores and loads for each register saved and restored.

There are two basic conventions in use to save registers: either at the call site or inside the procedure being called. *Caller saving* means that the calling procedure must save the registers that it wants preserved for access after the call, and thus the called procedure need not worry about registers. *Callee saving* is the opposite: the called procedure must save the registers it wants to use, leaving the caller unrestrained. There are times when caller save must be used because of access patterns to globally visible variables in two different procedures. For example, suppose we have a procedure P1 that calls procedure P2, and both procedures manipulate the

Figure A.17 Frequency of different types of compares in conditional branches. Less than (or equal) branches dominate this combination of compiler and architecture. These measurements include both the integer and floating-point compares in branches. The programs and computer used to collect these statistics are the same as those in [Figure A.8](#).

global variable x . If P1 had allocated x to a register, it must be sure to save x to a location known by P2 before the call to P2. A compiler's ability to discover when a called procedure may access register-allocated quantities is complicated by the possibility of separate compilation. Suppose P2 may not touch x but can call another procedure, P3, that may access x , yet P2 and P3 are compiled separately. Because of these complications, most compilers will conservatively caller save *any* variable that may be accessed during a call.

In the cases where either convention could be used, some programs will be more optimal with callee save and some will be more optimal with caller save. As a result, most real systems today use a combination of the two mechanisms. This convention is specified in an application binary interface (ABI) that sets down the basic rules as to which registers should be caller saved and which should be callee saved. Later in this appendix we will examine the mismatch between sophisticated instructions for automatically saving registers and the needs of the compiler.

Summary: Instructions for Control Flow

Control flow instructions are some of the most frequently executed instructions. Although there are many options for conditional branches, we would expect

branch addressing in a new architecture to be able to jump to hundreds of instructions either above or below the branch. This requirement suggests a PC-relative branch displacement of at least 8 bits. We would also expect to see register indirect and PC-relative addressing for jump instructions to support returns as well as many other features of current systems.

We have now completed our instruction architecture tour at the level seen by an assembly language programmer or compiler writer. We are leaning toward a load-store architecture with displacement, immediate, and register indirect addressing modes. These data are 8-, 16-, 32-, and 64-bit integers and 32- and 64-bit floating-point data. The instructions include simple operations, PC-relative conditional branches, jump and link instructions for procedure call, and register indirect jumps for procedure return (plus a few other uses).

Now we need to select how to represent this architecture in a form that makes it easy for the hardware to execute.

A.7

Encoding an Instruction Set

Clearly, the choices mentioned herein will affect how the instructions are encoded into a binary representation for execution by the processor. This representation affects not only the size of the compiled program but also the implementation of the processor, which must decode this representation to quickly find the operation and its operands. The operation is typically specified in one field, called the *opcode*. As we shall see, the important decision is how to encode the addressing modes with the operations.

This decision depends on the range of addressing modes and the degree of independence between opcodes and modes. Some older computers have one to five operands with 10 addressing modes for each operand (see [Figure A.6](#)). For such a large number of combinations, typically a separate *address specifier* is needed for each operand: the address specifier tells what addressing mode is used to access the operand. At the other extreme are load-store computers with only one memory operand and only one or two addressing modes; obviously, in this case, the addressing mode can be encoded as part of the opcode.

When encoding the instructions, the number of registers and the number of addressing modes both have a significant impact on the size of instructions, as the register field and addressing mode field may appear many times in a single instruction. In fact, for most instructions many more bits are consumed in encoding addressing modes and register fields than in specifying the opcode. The architect must balance several competing forces when encoding the instruction set:

1. The desire to have as many registers and addressing modes as possible.
2. The impact of the size of the register and addressing mode fields on the average instruction size and hence on the average program size.

3. A desire to have instructions encoded into lengths that will be easy to handle in a pipelined implementation. (The value of easily decoded instructions is discussed in [Appendix C](#) and [Chapter 3](#).) As a minimum, the architect wants instructions to be in multiples of bytes, rather than an arbitrary bit length. Many desktop and server architects have chosen to use a fixed-length instruction to gain implementation benefits while sacrificing average code size.

[Figure A.18](#) shows three popular choices for encoding the instruction set. The first we call *variable*, because it allows virtually all addressing modes to be with all operations. This style is best when there are many addressing modes and operations. The second choice we call *fixed*, because it combines the operation and the addressing mode into the opcode. Often fixed encoding will have only a single

Operation and no. of operands	Address specifier 1	Address field 1	...	Address specifier <i>n</i>	Address field <i>n</i>
----------------------------------	------------------------	--------------------	-----	-------------------------------	---------------------------

(A) Variable (e.g., Intel 80x86, VAX)

Operation	Address field 1	Address field 2	Address field 3
-----------	--------------------	--------------------	--------------------

(B) Fixed (e.g., RISC V, ARM, MIPS, PowerPC, SPARC)

Operation	Address specifier	Address field
-----------	----------------------	------------------

Operation	Address specifier 1	Address specifier 2	Address field
-----------	------------------------	------------------------	------------------

Operation	Address specifier	Address field 1	Address field 2
-----------	----------------------	--------------------	--------------------

(C) Hybrid (e.g., RISC V Compressed (RV32IC), IBM 360/370, microMIPS, Arm Thumb2)

Figure A.18 Three basic variations in instruction encoding: variable length, fixed length, and hybrid. The variable format can support any number of operands, with each address specifier determining the addressing mode and the length of the specifier for that operand. It generally enables the smallest code representation, because unused fields need not be included. The fixed format always has the same number of operands, with the addressing modes (if options exist) specified as part of the opcode. It generally results in the largest code size. Although the fields tend not to vary in their location, they will be used for different purposes by different instructions. The hybrid approach has multiple formats specified by the opcode, adding one or two fields to specify the addressing mode and one or two fields to specify the operand address.

size for all instructions; it works best when there are few addressing modes and operations. The trade-off between variable encoding and fixed encoding is size of programs versus ease of decoding in the processor. Variable tries to use as few bits as possible to represent the program, but individual instructions can vary widely in both size and the amount of work to be performed.

Let's look at an 80x86 instruction to see an example of the variable encoding:

```
add EAX, 1000(EBX)
```

The name `add` means a 32-bit integer add instruction with two operands, and this opcode takes 1 byte. An 80x86 address specifier is 1 or 2 bytes, specifying the source/destination register (EAX) and the addressing mode (displacement in this case) and base register (EBX) for the second operand. This combination takes 1 byte to specify the operands. When in 32-bit mode (see Appendix K), the size of the address field is either 1 byte or 4 bytes. Because 1000 is bigger than 2^8 , the total length of the instruction is

$$1 + 1 + 4 = 6 \text{ bytes}$$

The length of 80x86 instructions varies between 1 and 17 bytes. 80x86 programs are generally smaller than the RISC architectures, which use fixed formats (see Appendix K).

Given these two poles of instruction set design of variable and fixed, the third alternative immediately springs to mind: reduce the variability in size and work of the variable architecture but provide multiple instruction lengths to reduce code size. This *hybrid* approach is the third encoding alternative, and we'll see examples shortly.

Reduced Code Size in RISCs

As RISC computers started being used in embedded applications, the 32-bit fixed format became a liability because cost, and hence smaller code, are important. In response, several manufacturers offered a new hybrid version of their RISC instruction sets, with both 16-bit and 32-bit instructions. The narrow instructions support fewer operations, smaller address and immediate fields, fewer registers, and the two-address format rather than the classic three-address format of RISC computers. RISC-V offers such an extension, called RV32IC, the C standing for compressed. Common instruction occurrences, such as intermediates with small values and common ALU operations with the source and destination register being identical, are encoded in 16-bit formats. Appendix K gives two other examples, the ARM Thumb and microMIPS, which both claim a code size reduction of up to 40%.

In contrast to these instruction set extensions, IBM simply compresses its standard instruction set and then adds hardware to decompress instructions as they are fetched from memory on an instruction cache miss. Thus, the instruction cache contains full 32-bit instructions, but compressed code is kept in main memory, ROMs, and the disk. The advantage of a compressed format, such as RV32IC,

microMIPS and Thumb2 is that instruction caches act as if they are about 25% larger, while IBM's CodePack means that compilers need not be changed to handle different instruction sets and instruction decoding can remain simple.

CodePack starts with run-length encoding compression on any PowerPC program and then loads the resulting compression tables in a 2 KB table on chip. Hence, every program has its own unique encoding. To handle branches, which are no longer to an aligned word boundary, the PowerPC creates a hash table in memory that maps between compressed and uncompressed addresses. Like a TLB (see [Chapter 2](#)), it caches the most recently used address maps to reduce the number of memory accesses. IBM claims an overall performance cost of 10%, resulting in a code size reduction of 35%–40%.

Summary: Encoding an Instruction Set

Decisions made in the components of instruction set design discussed in previous sections determine whether the architect has the choice between variable and fixed instruction encodings. Given the choice, the architect more interested in code size than performance will pick variable encoding, and the one more interested in performance than code size will pick fixed encoding. RISC-V, MIPS, and ARM all have an instruction set extension that uses 16-bit instruction, as well as 32-bit; applications with serious code size constraints can opt to use the 16-bit variant to decrease code size. Appendix E gives 13 examples of the results of architects' choices. In [Appendix C](#) and [Chapter 3](#), the impact of variability on performance of the processor will be discussed further.

We have almost finished laying the groundwork for the RISC-V instruction set architecture that will be introduced in [Section A.9](#). Before we do that, however, it will be helpful to take a brief look at compiler technology and its effect on program properties.

A.8

Cross-Cutting Issues: The Role of Compilers

Today almost all programming is done in high-level languages for desktop and server applications. This development means that because most instructions executed are the output of a compiler, an instruction set architecture is essentially a compiler target. In earlier times for these applications, architectural decisions were often made to ease assembly language programming or for a specific kernel. Because the compiler will significantly affect the performance of a computer, understanding compiler technology today is critical to designing and efficiently implementing an instruction set.

Once it was popular to try to isolate the compiler technology and its effect on hardware performance from the architecture and its performance, just as it was popular to try to separate architecture from its implementation. This separation is essentially impossible with today's desktop compilers and computers. Architectural choices affect the quality of the code that can be generated for a computer and the complexity of building a good compiler for it, for better or for worse.

In this section, we discuss the critical goals in the instruction set primarily from the compiler viewpoint. It starts with a review of the anatomy of current compilers. Next we discuss how compiler technology affects the decisions of the architect, and how the architect can make it hard or easy for the compiler to produce good code. We conclude with a review of compilers and multimedia operations, which unfortunately is a bad example of cooperation between compiler writers and architects.

The Structure of Recent Compilers

To begin, let's look at what optimizing compilers are like today. Figure A.19 shows the structure of recent compilers.

A compiler writer's first goal is correctness—all valid programs must be compiled correctly. The second goal is usually speed of the compiled code. Typically, a whole set of other goals follows these two, including fast compilation, debugging support, and interoperability among languages. Normally, the passes

Figure A.19 Compilers typically consist of two to four passes, with more highly optimizing compilers having more passes. This structure maximizes the probability that a program compiled at various levels of optimization will produce the same output when given the same input. The optimizing passes are designed to be optional and may be skipped when faster compilation is the goal and lower-quality code is acceptable. A *pass* is simply one phase in which the compiler reads and transforms the entire program. (The term *phase* is often used interchangeably with *pass*.) Because the optimizing passes are separated, multiple languages can use the same optimizing and code generation passes. Only a new front end is required for a new language.

in the compiler transform higher-level, more abstract representations into progressively lower-level representations. Eventually it reaches the instruction set. This structure helps manage the complexity of the transformations and makes writing a bug-free compiler easier.

The complexity of writing a correct compiler is a major limitation on the amount of optimization that can be done. Although the multiple-pass structure helps reduce compiler complexity, it also means that the compiler must order and perform some transformations before others. In the diagram of the optimizing compiler in [Figure A.19](#), we can see that certain high-level optimizations are performed long before it is known what the resulting code will look like. Once such a transformation is made, the compiler can't afford to go back and revisit all steps, possibly undoing transformations. Such iteration would be prohibitive, both in compilation time and in complexity. Thus, compilers make assumptions about the ability of later steps to deal with certain problems. For example, compilers usually have to choose which procedure calls to expand inline before they know the exact size of the procedure being called. Compiler writers call this problem the *phase-ordering problem*.

How does this ordering of transformations interact with the instruction set architecture? A good example occurs with the optimization called *global common subexpression elimination*. This optimization finds two instances of an expression that compute the same value and saves the value of the first computation in a temporary. It then uses the temporary value, eliminating the second computation of the common expression.

For this optimization to be significant, the temporary must be allocated to a register. Otherwise, the cost of storing the temporary in memory and later reloading it may negate the savings gained by not recomputing the expression. There are, in fact, cases where this optimization actually slows down code when the temporary is not register allocated. Phase ordering complicates this problem because register allocation is typically done near the end of the global optimization pass, just before code generation. Thus, an optimizer that performs this optimization must *assume* that the register allocator will allocate the temporary to a register.

Optimizations performed by modern compilers can be classified by the style of the transformation, as follows:

- *High-level optimizations* are often done on the source with output fed to later optimization passes.
- *Local optimizations* optimize code only within a straight-line code fragment (called a *basic block* by compiler people).
- *Global optimizations* extend the local optimizations across branches and introduce a set of transformations aimed at optimizing loops.
- *Register allocation* associates registers with operands.
- *Processor-dependent optimizations* attempt to take advantage of specific architectural knowledge.

Register Allocation

Because of the central role that register allocation plays, both in speeding up the code and in making other optimizations useful, it is one of the most important—if not the most important—of the optimizations. Register allocation algorithms today are based on a technique called *graph coloring*. The basic idea behind graph coloring is to construct a graph representing the possible candidates for allocation to a register and then to use the graph to allocate registers. Roughly speaking, the problem is how to use a limited set of colors so that no two adjacent nodes in a dependency graph have the same color. The emphasis in the approach is to achieve 100% register allocation of active variables. The problem of coloring a graph in general can take exponential time as a function of the size of the graph (NP-complete). There are heuristic algorithms, however, that work well in practice, yielding close allocations that run in near-linear time.

Graph coloring works best when there are at least 16 (and preferably more) general-purpose registers available for global allocation for integer variables and additional registers for floating point. Unfortunately, graph coloring does not work very well when the number of registers is small because the heuristic algorithms for coloring the graph are likely to fail.

Impact of Optimizations on Performance

It is sometimes difficult to separate some of the simpler optimizations—local and processor-dependent optimizations—from transformations done in the code generator. Examples of typical optimizations are given in [Figure A.20](#). The last column of [Figure A.20](#) indicates the frequency with which the listed optimizing transforms were applied to the source program.

[Figure A.21](#) shows the effect of various optimizations on instructions executed for two programs. In this case, optimized programs executed roughly 25%–90% fewer instructions than unoptimized programs. The figure illustrates the importance of looking at optimized code before suggesting new instruction set features, because a compiler might completely remove the instructions the architect was trying to improve.

The Impact of Compiler Technology on the Architect's Decisions

The interaction of compilers and high-level languages significantly affects how programs use an instruction set architecture. There are two important questions: how are variables allocated and addressed? How many registers are needed to allocate variables appropriately? To address these questions, we must look at the three separate areas in which current high-level languages allocate their data:

Optimization name	Explanation	Percentage of the total number of optimizing transforms
<i>High-level</i>	<i>At or near the source level; processor-independent</i>	
Procedure integration	Replace procedure call by procedure body	N.M.
<i>Local</i>	<i>Within straight-line code</i>	
Common subexpression elimination	Replace two instances of the same computation by single copy	18%
Constant propagation	Replace all instances of a variable that is assigned a constant with the constant	22%
Stack height reduction	Rearrange expression tree to minimize resources needed for expression evaluation	N.M.
<i>Global</i>	<i>Across a branch</i>	
Global common subexpression elimination	Same as local, but this version crosses branches	13%
Copy propagation	Replace all instances of a variable A that has been assigned X (i.e., $A = X$) with X	11%
Code motion	Remove code from a loop that computes same value each iteration of the loop	16%
Induction variable elimination	Simplify/eliminate array addressing calculations within loops	2%
<i>Processor-dependent</i>	<i>Depends on processor knowledge</i>	
Strength reduction	Many examples, such as replace multiply by a constant with adds and shifts	N.M.
Pipeline scheduling	Reorder instructions to improve pipeline performance	N.M.
Branch offset optimization	Choose the shortest branch displacement that reaches target	N.M.

Figure A.20 Major types of optimizations and examples in each class. These data tell us about the relative frequency of occurrence of various optimizations. The third column lists the static frequency with which some of the common optimizations are applied in a set of 12 small Fortran and Pascal programs. There are nine local and global optimizations done by the compiler included in the measurement. Six of these optimizations are covered in the figure, and the remaining three account for 18% of the total static occurrences. The abbreviation *N.M.* means that the number of occurrences of that optimization was not measured. Processor-dependent optimizations are usually done in a code generator, and none of those was measured in this experiment. The percentage is the portion of the static optimizations that are of the specified type. Data from Chow, F.C., 1983. *A Portable Machine-Independent Global Optimizer—Design and Measurements* (Ph.D. thesis). Stanford University, Palo Alto, CA (collected using the Stanford UCODE compiler).

- The *stack* is used to allocate local variables. The stack is grown or shrunk on procedure call or return, respectively. Objects on the stack are addressed relative to the stack pointer and are primarily scalars (single variables) rather than arrays. The stack is used for activation records, *not* as a stack for evaluating expressions. Hence, values are almost never pushed or popped on the stack.

Figure A.21 Change in instruction count for the programs *lucas* and *mcf* from the SPEC2000 as compiler optimization levels vary. Level 0 is the same as unoptimized code. Level 1 includes local optimizations, code scheduling, and local register allocation. Level 2 includes global optimizations, loop transformations (software pipelining), and global register allocation. Level 3 adds procedure integration. These experiments were performed on Alpha compilers.

- The *global data area* is used to allocate statically declared objects, such as global variables and constants. A large percentage of these objects are arrays or other aggregate data structures.
- The *heap* is used to allocate dynamic objects that do not adhere to a stack discipline. Objects in the heap are accessed with pointers and are typically not scalars.

Register allocation is much more effective for stack-allocated objects than for global variables, and register allocation is essentially impossible for heap-allocated objects because they are accessed with pointers. Global variables and some stack variables are impossible to allocate because they are *aliased*—there are multiple ways to refer to the address of a variable, making it illegal to put it into a register. (Most heap variables are effectively aliased for today’s compiler technology.)

For example, consider the following code sequence, where `&` returns the address of a variable and `*` dereferences a pointer:

```
p=&a - gets address of a in p
a=... - assigns to a directly
*p=... - uses p to assign to a
...a... - accesses a
```

The variable *a* could not be register allocated across the assignment to **p* without generating incorrect code. Aliasing causes a substantial problem because it is

often difficult or impossible to decide what objects a pointer may refer to. A compiler must be conservative; some compilers will not allocate *any* local variables of a procedure in a register when there is a pointer that may refer to *one* of the local variables.

How the Architect Can Help the Compiler Writer

Today, the complexity of a compiler does not come from translating simple statements like $A = B + C$. Most programs are *locally simple*, and simple translations work fine. Rather, complexity arises because programs are large and globally complex in their interactions, and because the structure of compilers means decisions are made one step at a time about which code sequence is best.

Compiler writers often are working under their own corollary of a basic principle in architecture: *make the frequent cases fast and the rare case correct*. That is, if we know which cases are frequent and which are rare, and if generating code for both is straightforward, then the quality of the code for the rare case may not be very important—but it must be correct!

Some instruction set properties help the compiler writer. These properties should not be thought of as hard-and-fast rules, but rather as guidelines that will make it easier to write a compiler that will generate efficient and correct code.

- *Provide regularity*—Whenever it makes sense, the three primary components of an instruction set—the operations, the data types, and the addressing modes—should be *orthogonal*. Two aspects of an architecture are said to be orthogonal if they are independent. For example, the operations and addressing modes are orthogonal if, for every operation to which one addressing mode can be applied, all addressing modes are applicable. This regularity helps simplify code generation and is particularly important when the decision about what code to generate is split into two passes in the compiler. A good counterexample of this property is restricting what registers can be used for a certain class of instructions. Compilers for special-purpose register architectures typically get stuck in this dilemma. This restriction can result in the compiler finding itself with lots of available registers, but none of the right kind!
- *Provide primitives, not solutions*—Special features that “match” a language construct or a kernel function are often unusable. Attempts to support high-level languages may work only with one language or do more or less than is required for a correct and efficient implementation of the language. An example of how such attempts have failed is given in [Section A.10](#).
- *Simplify trade-offs among alternatives*—One of the toughest jobs a compiler writer has is figuring out what instruction sequence will be best for every segment of code that arises. In earlier days, instruction counts or total code size might have been good metrics, but—as we saw in [Chapter 1](#)—this is no longer

true. With caches and pipelining, the trade-offs have become very complex. Anything the designer can do to help the compiler writer understand the costs of alternative code sequences would help improve the code. One of the most difficult instances of complex trade-offs occurs in a register-memory architecture in deciding how many times a variable should be referenced before it is cheaper to load it into a register. This threshold is hard to compute and, in fact, may vary among models of the same architecture.

- *Provide instructions that bind the quantities known at compile time as constants*—A compiler writer hates the thought of the processor interpreting at runtime a value that was known at compile time. Good counterexamples of this principle include instructions that interpret values that were fixed at compile time. For instance, the VAX procedure call instruction (`call`s) dynamically interprets a mask saying what registers to save on a call, but the mask is fixed at compile time (see [Section A.10](#)).

Compiler Support (or Lack Thereof) for Multimedia Instructions

Alas, the designers of the SIMD instructions (see Section 4.3 in [Chapter 4](#)) basically ignored the previous subsection. These instructions tend to be solutions, not primitives; they are short of registers; and the data types do not match existing programming languages. Architects hoped to find an inexpensive solution that would help some users, but often only a few low-level graphics library routines use them.

The SIMD instructions are really an abbreviated version of an elegant architecture style that has its own compiler technology. As explained in Section 4.2, *vector architectures* operate on vectors of data. Invented originally for scientific codes, multimedia kernels are often vectorizable as well, albeit often with shorter vectors. As Section 4.3 suggests, we can think of Intel's MMX and SSE or PowerPC's AltiVec, or the RISC-V P extension, as simply short vector computers: MMX with vectors of eight 8-bit elements, four 16-bit elements, or two 32-bit elements, and AltiVec with vectors twice that length. They are implemented as simply adjacent, narrow elements in wide registers.

These microprocessor architectures build the vector register size into the architecture: the sum of the sizes of the elements is limited to 64 bits for MMX and 128 bits for AltiVec. When Intel decided to expand to 128-bit vectors, it added a whole new set of instructions, called streaming SIMD extension (SSE).

A major advantage of vector computers is hiding latency of memory access by loading many elements at once and then overlapping execution with data transfer. The goal of vector addressing modes is to collect data scattered about memory, place them in a compact form so that they can be operated on efficiently, and then place the results back where they belong.

Vector computers include *strided addressing* and *gather/scatter addressing* (see Section 4.2) to increase the number of programs that can be vectorized. Strided addressing skips a fixed number of words between each access, so sequential addressing is often called *unit stride addressing*. Gather and scatter find their

addresses in another vector register: think of it as register indirect addressing for vector computers. From a vector perspective, in contrast, these short-vector SIMD computers support only unit strided accesses: memory accesses load or store all elements at once from a single wide memory location. Because the data for multimedia applications are often streams that start and end in memory, strided and gather/scatter addressing modes are essential to successful vectorization (see Section 4.7).

Example As an example, compare a vector computer with MMX for color representation conversion of pixels from RGB (red, green, blue) to YUV (luminosity chrominance), with each pixel represented by 3 bytes. The conversion is just three lines of C code placed in a loop:

```
Y = (9798*R + 19235*G + 3736*B) / 32768;
U = (-4784*R + 9437*G + 4221*B) / 32768 + 128;
V = (20218*R - 16941*G + 3277*B) / 32768 + 128;
```

A 64-bit-wide vector computer can calculate 8 pixels simultaneously. One vector computer for media with strided addresses takes

- 3 vector loads (to get RGB)
- 3 vector multiplies (to convert R)
- 6 vector multiply adds (to convert G and B)
- 3 vector shifts (to divide by 32,768)
- 2 vector adds (to add 128)
- 3 vector stores (to store YUV)

The total is 20 instructions to perform the 20 operations in the previous C code to convert 8 pixels ([Kozyrakis, 2000](#)). (Because a vector might have 32 64-bit elements, this code actually converts up to 32×8 or 256 pixels.)

In contrast, Intel's website shows that a library routine to perform the same calculation on 8 pixels takes 116 MMX instructions plus 6 80x86 instructions ([Intel, 2001](#)). This six-fold increase in instructions is due to the large number of instructions to load and unpack RGB pixels and to pack and store YUV pixels, because there are no strided memory accesses.

Having short, architecture-limited vectors with few registers and simple memory addressing modes makes it more difficult to use vectorizing compiler technology. Hence, these SIMD instructions are more likely to be found in hand-coded libraries than in compiled code.

Summary: The Role of Compilers

This section leads to several recommendations. First, we expect a new instruction set architecture to have at least 16 general-purpose registers—not counting

separate registers for floating-point numbers—to simplify allocation of registers using graph coloring. The advice on orthogonality suggests that all supported addressing modes apply to all instructions that transfer data. Finally, the last three pieces of advice—provide primitives instead of solutions, simplify trade-offs between alternatives, don’t bind constants at runtime—all suggest that it is better to err on the side of simplicity. In other words, understand that less is more in the design of an instruction set. Alas, SIMD extensions are more an example of good marketing than of outstanding achievement of hardware–software co-design.

A.9

Putting It All Together: The RISC-V Architecture

In this section we describe the load-store architecture called RISC-V. RISC-V is a freely licensed open standard, similar to many of the RISC architectures, and based on observations similar to those covered in the last sections. (In Section M.3 we discuss how and why these architectures became popular.) RISC-V builds on 30 years of experience with RISC architectures and “cleans up” most of the short-term inclusions and omissions, leading to an architecture that is easier and more efficient to implement. RISC-V provides both a 32-bit and a 64-bit instruction set, as well as a variety of extensions for features like floating point; these extensions can be added to either the 32-bit or 64-bit base instruction set. We discuss a 64-bit version of RISC-V, RV64, which is a superset of the 32-bit version RV32.

Reviewing our expectations from each section, for desktop and server applications:

- [Section A.2](#)—Use general-purpose registers with a load-store architecture.
- [Section A.3](#)—Support these addressing modes: displacement (with an address offset size of 12–16 bits), immediate (size 8–16 bits), and register indirect.
- [Section A.4](#)—Support these data sizes and types: 8-, 16-, 32-, and 64-bit integers and 64-bit IEEE 754 floating-point numbers.
- [Section A.5](#)—Support these simple instructions, because they will dominate the number of instructions executed: load, store, add, subtract, move register-register, and shift.
- [Section A.6](#)—Compare equal, compare not equal, compare less, branch (with a PC-relative address at least 8 bits long), jump, call, and return.
- [Section A.7](#)—Use fixed instruction encoding if interested in performance, and use variable instruction encoding if interested in code size. In some low-end, embedded applications, with small or only one-level caches, larger code size may have significant performance implications. ISAs that provide a compressed instruction set extension provide a way of addressing this difference.
- [Section A.8](#)—Provide at least 16, and preferably 32, general-purpose registers, be sure all addressing modes apply to all data transfer instructions, and aim for

a minimalist instruction set. This section didn't cover floating-point programs, but they often use separate floating-point registers. The justification is to increase the total number of registers without raising problems in the instruction format or in the speed of the general-purpose register file. This compromise, however, is not orthogonal.

We introduce RISC-V by showing how it follows these recommendations. Like its RISC predecessors, RISC-V emphasizes

- A simple load-store instruction set.
- Design for pipelining efficiency (discussed in [Appendix C](#)), including a fixed instruction set encoding.
- Efficiency as a compiler target.

RISC-V provides a good architectural model for study, not only because of the popularity of this type of processor, but also because it is an easy architecture to understand. We will use this architecture again in [Appendix C](#) and in [Chapter 3](#), and it forms the basis for a number of exercises and programming projects.

RISC-V Instruction Set Organization

The RISC-V instruction set is organized as three base instruction sets that support 32-bit or 64-bit integers, and a variety of optional extensions to one of the base instruction sets. This allows RISC-V to be implemented for a wide range of potential applications from a small embedded processor with a minimal budget for logic and memory that likely costs \$1 or less, to high-end processor configurations with full support for floating point, vectors, and multiprocessor configurations. [Figure A.22](#) summarizes the three base instruction sets and the instruction set extensions with their basic functionality. For purposes of this text, we use RV64IMAFD (also known as RV64G, for short) in examples. RV32G is the 32-bit subset of the 64-bit architecture RV64G.

Registers for RISC-V

RV64G has 32 64-bit general-purpose registers (GPRs), named x0, x1, ..., x31. GPRs are also sometimes known as *integer registers*. Additionally, with the F and D extensions for floating point that are part of RV64G, come a set of 32 floating-point registers (FPRs), named f0, f1, ..., f31, which can hold 32 single-precision (32-bit) values or 32 double-precision (64-bit) values. (When holding one single-precision number, the other half of the FPR is unused.) Both single- and double-precision floating-point operations (32-bit and 64-bit) are provided.

The value of x0 is always 0. We shall see later how we can use this register to synthesize a variety of useful operations from a simple instruction set.

A few special registers can be transferred to and from the general-purpose registers. An example is the floating-point status register, used to hold information

Name of base or extension	Functionality
RV32I	Base 32-bit integer instruction set with 32 registers
RV32E	Base 32-bit instruction set but with only 16 registers; intended for very low-end embedded applications
RV64I	Base 64-bit instruction set; all registers are 64-bits, and instructions to move 64-bit from/to the registers (LD and SD) are added
M	Adds integer multiply and divide instructions
A	Adds atomic instructions needed for concurrent processing; see Chapter 5
F	Adds single precision (32-bit) IEEE floating point, includes 32 32-bit floating point registers, instructions to load and store those registers and operate on them
D	Extends floating point to double precision, 64-bit, making the registers 64-bits, adding instructions to load, store, and operate on the registers
Q	Further extends floating point to add support for quad precision, adding 128-bit operations
L	Adds support for 64- and 128-bit decimal floating point for the IEEE standard
C	Defines a compressed version of the instruction set intended for small-memory-sized embedded applications. Defines 16-bit versions of common RV32I instructions
V	A future extension to support vector operations (see Chapter 4)
B	A future extension to support operations on bit fields
T	A future extension to support transactional memory
P	An extension to support packed SIMD instructions: see Chapter 4
RV128I	A future base instruction set providing a 128-bit address space

Figure A.22 RISC-V has three base instructions sets (and a reserved spot for a future fourth); all the extensions extend one of the base instruction sets. An instruction set is thus named by the base name followed by the extensions. For example, RISC-V64IMAFD refers to the base 64-bit instruction set with extensions M, A, F, and D. For consistency of naming and software, this combination is given the abbreviated name: RV64G, and we use RV64G through most of this text.

about the results of floating-point operations. There are also instructions for moving between an FPR and a GPR.

Data Types for RISC-V

The data types are 8-bit bytes, 16-bit half words, 32-bit words, and 64-bit double-words for integer data and 32-bit single precision and 64-bit double precision for floating point. Half words were added because they are found in languages like C

and are popular in some programs, such as the operating systems, concerned about size of data structures. They will also become more popular if Unicode becomes widely used.

The RV64G operations work on 64-bit integers and 32- or 64-bit floating point. Bytes, half words, and words are loaded into the general-purpose registers with either zeros or the sign bit replicated to fill the 64 bits of the GPRs. Once loaded, they are operated on with the 64-bit integer operations.

Addressing Modes for RISC-V Data Transfers

The only data addressing modes are immediate and displacement, both with 12-bit fields. Register indirect is accomplished simply by placing 0 in the 12-bit displacement field, and limited absolute addressing with a 12-bit field is accomplished by using register 0 as the base register. Embracing zero gives us four effective modes, although only two are supported in the architecture.

RV64G memory is byte addressable with a 64-bit address and uses Little Endian byte numbering. As it is a load-store architecture, all references between memory and either GPRs or FPRs are through loads or stores. Supporting the data types mentioned herein, memory accesses involving GPRs can be to a byte, half word, word, or double word. The FPRs may be loaded and stored with single-precision or double-precision numbers. Memory accesses need not be aligned; however, it may be that unaligned accesses run extremely slow. In practice, programmers and compilers would be stupid to use unaligned accesses.

RISC-V Instruction Format

Because RISC-V has just two addressing modes, these can be encoded into the opcode. Following the advice on making the processor easy to pipeline and decode, all instructions are 32 bits with a 7-bit primary opcode. Figure A.23 shows the instruction layout of the four major instruction types. These formats are simple while providing 12-bit fields for displacement addressing, immediate constants, or PC-relative branch addresses.

Figure A.23 The RISC-V instruction layout. There are two variations on these formats, called the SB and UJ formats; they deal with a slightly different treatment for immediate fields.

Instruction format	Primary use	rd	rs1	rs2	Immediate
R-type	Register-register ALU instructions	Destination	First source	Second source	
I-type	ALU immediates Load	Destination	First source base register		Value displacement
S-type	Store Compare and branch		Base register first source	Data source to store second source	Displacement offset
U-type	Jump and link Jump and link register	Register destination for return PC	Target address for jump and link register		Target address for jump and link

Figure A.24 The use of instruction fields for each instruction type. Primary use shows the major instructions that use the format. A blank indicates that the corresponding field is not present in this instruction type. The I-format is used for both loads and ALU immediates, with the 12-bit immediate holding either the value for an immediate or the displacement for a load. Similarly, the S-format encodes both store instructions (where the first source register is the base register and the second contains the register source for the value to store) and compare and branch instructions (where the register fields contain the sources to compare and the immediate field specifies the offset of the branch target). There are actually two other formats: SB and UJ that follow the same basic organization as S and J, but slightly modify the interpretation of the immediate fields.

The instruction formats and the use of the instruction fields is described in [Figure A.24](#). The opcode specifies the general instruction type (ALU instruction, ALU immediate, load, store, branch, or jump), while the funct fields are used for specific operations. For example, an ALU instruction is encoded with a single opcode with the funct field dictating the exact operation: add, subtract, and, etc. Notice that several formats encode multiple types of instructions, including the use of the I-format for both ALU immediates and loads, and the use of the S-format for stores and conditional branches.

RISC-V Operations

RISC-V (or more properly RV64G) supports the list of simple operations recommended herein plus a few others. There are four broad classes of instructions: loads and stores, ALU operations, branches and jumps, and floating-point operations.

Any of the general-purpose or floating-point registers may be loaded or stored, except that loading x0 has no effect. [Figure A.25](#) gives examples of the load and store instructions. Single-precision floating-point numbers occupy half a floating-point register. Conversions between single and double precision must be done explicitly. The floating-point format is IEEE 754 (see Appendix J). A list of all the RV64G instructions appears in [Figure A.28](#) (page A.42).

Example instruction	Instruction name	Meaning
ld x1,80(x2)	Load doubleword	$\text{Regs}[\text{x1}] \leftarrow \text{Mem}[80 + \text{Regs}[\text{x2}]]$
lw x1,60(x2)	Load word	$\text{Regs}[\text{x1}] \leftarrow_{64} \text{Mem}[60 + \text{Regs}[\text{x2}]]_0^{32} \text{###}$ $\text{Mem}[60 + \text{Regs}[\text{x2}]]$
lwu x1,60(x2)	Load word unsigned	$\text{Regs}[\text{x1}] \leftarrow_{64} 0^{32} \text{###} \text{Mem}[60 + \text{Regs}[\text{x2}]]$
lb x1,40(x3)	Load byte	$\text{Regs}[\text{x1}] \leftarrow_{64} (\text{Mem}[40 + \text{Regs}[\text{x3}]]_0)^{56} \text{###}$ $\text{Mem}[40 + \text{Regs}[\text{x3}]]$
lbu x1,40(x3)	Load byte unsigned	$\text{Regs}[\text{x1}] \leftarrow_{64} 0^{56} \text{###} \text{Mem}[40 + \text{Regs}[\text{x3}]]$
lh x1,40(x3)	Load half word	$\text{Regs}[\text{x1}] \leftarrow_{64} (\text{Mem}[40 + \text{Regs}[\text{x3}]]_0)^{48} \text{###}$ $\text{Mem}[40 + \text{Regs}[\text{x3}]]$
flw f0,50(x3)	Load FP single	$\text{Regs}[\text{f0}] \leftarrow_{64} \text{Mem}[50 + \text{Regs}[\text{x3}]] \text{###} 0^{32}$
fld f0,50(x2)	Load FP double	$\text{Regs}[\text{f0}] \leftarrow_{64} \text{Mem}[50 + \text{Regs}[\text{x2}]]$
sd x2,400(x3)	Store double	$\text{Mem}[400 + \text{Regs}[\text{x3}]] \leftarrow_{64} \text{Regs}[\text{x2}]$
sw x3,500(x4)	Store word	$\text{Mem}[500 + \text{Regs}[\text{x4}]] \leftarrow_{32} \text{Regs}[\text{x3}]_{32..63}$
fsd f0,40(x3)	Store FP single	$\text{Mem}[40 + \text{Regs}[\text{x3}]] \leftarrow_{32} \text{Regs}[\text{f0}]_{0..31}$
fsw f0,40(x3)	Store FP double	$\text{Mem}[40 + \text{Regs}[\text{x3}]] \leftarrow_{64} \text{Regs}[\text{f0}]$
sh x3,502(x2)	Store half	$\text{Mem}[502 + \text{Regs}[\text{x2}]] \leftarrow_{16} \text{Regs}[\text{x3}]_{48..63}$
sb x2,41(x3)	Store byte	$\text{Mem}[41 + \text{Regs}[\text{x3}]] \leftarrow_8 \text{Regs}[\text{x2}]_{56..63}$

Figure A.25 The load and store instructions in RISC-V. Loads shorter than 64 bits are available in both sign-extended and zero-extended forms. All memory references use a single addressing mode. Of course, both loads and stores are available for all the data types shown. Because RV64G supports double precision floating point, all single precision floating point loads must be aligned in the FP register, which are 64-bits wide.

To understand these figures we need to introduce a few additional extensions to our C description language used initially on page A-9:

- A subscript is appended to the symbol \leftarrow whenever the length of the datum being transferred might not be clear. Thus, \leftarrow_n means transfer an n -bit quantity. We use $x, y \leftarrow z$ to indicate that z should be transferred to x and y .
- A subscript is used to indicate selection of a bit from a field. Bits are labeled from the most-significant bit starting at 0. The subscript may be a single digit (e.g., $\text{Regs}[\text{x4}]_0$ yields the sign bit of x4) or a subrange (e.g., $\text{Regs}[\text{x3}]_{56..63}$ yields the least-significant byte of x3).
- The variable `Mem`, used as an array that stands for main memory, is indexed by a byte address and may transfer any number of bytes.
- A superscript is used to replicate a field (e.g., 0^{48} yields a field of zeros of length 48 bits).
- The symbol `###` is used to concatenate two fields and may appear on either side of a data transfer, and the symbols \ll and \gg shift the first operand left or right by the amount of the second operand.

Example instrumction	Instruction name	Meaning
<code>add x1,x2,x3</code>	Add	$\text{Regs}[x1] \leftarrow \text{Regs}[x2] + \text{Regs}[x3]$
<code>addi x1,x2,3</code>	Add immediate unsigned	$\text{Regs}[x1] \leftarrow \text{Regs}[x2] + 3$
<code>lui x1,42</code>	Load upper immediate	$\text{Regs}[x1] \leftarrow 0^{32} \# \# 42 \# \# 0^{12}$
<code>sll x1,x2,5</code>	Shift left logical	$\text{Regs}[x1] \leftarrow \text{Regs}[x2] \ll 5$
<code>slt x1,x2,x3</code>	Set less than	$\text{if } (\text{Regs}[x2] < \text{Regs}[x3])$ $\text{Regs}[x1] \leftarrow 1 \text{ else } \text{Regs}[x1] \leftarrow 0$

Figure A.26 The basic ALU instructions in RISC-V are available both with register-register operands and with one immediate operand. LUI uses the U-format that employs the rs1 field as part of the immediate, yielding a 20-bit immediate.

As an example, assuming that x8 and x10 are 32-bit registers:

$$\text{Regs}[x10] \leftarrow_{64} (\text{Mem}[\text{Regs}[x8]]_0)^{32} \# \# \text{Mem}[\text{Regs}[R8]]$$

means that the word at the memory location addressed by the contents of register x8 is sign-extended to form a 64-bit quantity that is stored into register x10.

All ALU instructions are register-register instructions. Figure A.26 gives some examples of the arithmetic/logical instructions. The operations include simple arithmetic and logical operations: add, subtract, AND, OR, XOR, and shifts. Immediate forms of all these instructions are provided using a 12-bit sign-extended immediate. The operation LUI (load upper immediate) loads bits 12–31 of a register, sign-extends the immediate field to the upper 32-bits, and sets the low-order 12-bits of the register to 0. LUI allows a 32-bit constant to be built in two instructions, or a data transfer using any constant 32-bit address in one extra instruction.

As mentioned herein, x0 is used to synthesize popular operations. Loading a constant is simply an add immediate where the source operand is x0, and a register-register move is simply an add (or an or) where one of the sources is x0. (We sometimes use the mnemonic li, standing for load immediate, to represent the former, and the mnemonic mv for the latter.)

RISC-V Control Flow Instructions

Control is handled through a set of jumps and a set of branches, and Figure A.27 gives some typical branch and jump instructions. The two jump instructions (jump and link and jump and link register) are unconditional transfers and always store the “link,” which is the address of the instruction sequentially following the jump instruction, in the register specified by the rd field. In the event that the link address is not needed, the rd field can simply be set to x0, which results in a typical unconditional jump. The two jump instructions are differentiated by whether the address is computed by adding an immediate field to the PC or by adding the immediate

Example instruction	Instruction name	Meaning
jal x1,offset	Jump and link	$\text{Regs}[x1] \leftarrow \text{PC} + 4; \text{PC} \leftarrow \text{PC} + (\text{offset} \ll 1)$
jalr x1,x2,offset	Jump and link register	$\text{Regs}[x1] \leftarrow \text{PC} + 4; \text{PC} \leftarrow \text{Regs}[x2] + \text{offset}$
beq x3,x4,offset	Branch equal zero	if ($\text{Regs}[x3] == \text{Regs}[x4]$) $\text{PC} \leftarrow \text{PC} + (\text{offset} \ll 1)$
bgt x3,x4,name	Branch not equal zero	if ($\text{Regs}[x3] > \text{Regs}[x4]$) $\text{PC} \leftarrow \text{PC} + (\text{offset} \ll 1)$

Figure A.27 Typical control flow instructions in RISC-V. All control instructions, except jumps to an address in a register, are PC-relative.

field to the contents of a register. The offset is interpreted as a half word offset for compatibility with the compressed instruction set, R64C, which includes 16-bit instructions.

All branches are conditional. The branch condition is specified by the instruction, and any arithmetic comparison (equal, greater than, less than, and their inverses) is permitted. The branch-target address is specified with a 12-bit signed offset that is shifted left one place (to get 16-bit alignment) and then added to the current program counter. Branches based on the contents of the floating point registers are implemented by executing a floating point comparison (e.g., feq.d or fle.d), which sets an integer register to 0 or 1 based on the comparison, and then executing a beq or bne with x0 as an operand.

The observant reader will have noticed that there are very few 64-bit only instructions in RV64G. Primarily, these are the 64-bit loads and stores and versions of 32-bit, 16-bit, and 8-bit loads that do not sign extend (the default is to sign-extend). To support 32-bit modular arithmetic without additional instructions, there are versions of the instructions that ignore the upper 32 bits of a 64-bit register, such as add and subtract word (addw, subw). Amazingly, everything else just works.

RISC-V Floating-Point Operations

Floating-point instructions manipulate the floating-point registers and indicate whether the operation to be performed is single or double precision. The floating-point operations are add, subtract, multiply, divide, square root, as well as fused multiply-add and multiply-subtract. All floating point instructions begin with the letter *f* and use the suffix *d* for double precision and *s* for single precision (e.g., fadd.d, fadd.s, fmul.d, fmul.s, fmadd.d, fmadd.s). Floating-point compares set an integer register based on the comparison, similarly to the integer instruction set-less-than and set-great-than.

In addition to floating-point loads and stores (flw, fsw, fld, fsd), instructions are provided for converting between different FP precisions, for moving between integer and FP registers (fmv), and for converting between floating point and integer (fcvt, which uses the integer registers for source or destination as appropriate).

Figure A.28 contains a list of nearly all the RV64G instructions and a summary of their meaning.

Instruction type/opcode	Instruction meaning
<i>Data transfers</i>	<i>Move data between registers and memory, or between the integer and FP; only memory address mode is 12-bit displacement + contents of a GPR</i>
lb, lbu, sb	Load byte, load byte unsigned, store byte (to/from integer registers)
lh, lhu, sh	Load half word, load half word unsigned, store half word (to/from integer registers)
lw, lwu, sw	Load word, store word (to/from integer registers)
ld, sd	Load doubleword, store doubleword
<i>Arithmetic/logical</i>	<i>Operations on data in GPRs. Word versions ignore upper 32 bits</i>
add, addi, addw, addiw, sub, subi, subw, subiw	Add and subtract, with both word and immediate versions
slt, sltu, slti, sltiu	set-less-than with signed and unsigned, and immediate
and, or, xor, andi, ori, xori	and, or, xor, both register-register and register-immediate
lui	Load upper immediate: loads bits 31..12 of a register with the immediate value. Upper 32 bits are set to 0
auipc	Sums an immediate and the upper 20-bits of the PC into a register; used for building a branch to any 32-bit address
sll, srl, sra, slli, srli, srai, sllw, slliw, srli, srliw, srai, sraiw	Shifts: logical shift left and right and arithmetic shift right, both immediate and word versions (word versions leave the upper 32 bit untouched)
mul, mulw, mulh, mulhsu, mulhu, div, divw, divu, rem, remu, remw, remuw	Integer multiply, divide, and remainder, signed and unsigned with support for 64-bit products in two instructions. Also word versions
<i>Control</i>	<i>Conditional branches and jumps; PC-relative or through register</i>
beq, bne, blt, bge, bltu, bgeu	Branch based on compare of two registers, equal, not equal, less than, greater or equal, signed and unsigned
jal, jalr	Jump and link address relative to a register or the PC
<i>Floating point</i>	<i>All FP operation appear in double precision (.d) and single (.s)</i>
flw, fld, fsw, fsd	Load, store, word (single precision), doubleword (double precision)
fadd, fsub, fmult, fiv, fsqrt, fmadd, fmsub, fnmadd, fnmsub, fmin, fmax, fsgn, fsgnj, fsjnx	Add, subtract, multiply, divide, square root, multiply-add, multiply-subtract, negate multiply-add, negate multiply-subtract, maximum, minimum, and instructions to replace the sign bit. For single precision, the opcode is followed by: .s, for double precision: .d. Thus fadd.s, fadd.d
feq, flt, fle	Compare two floating point registers; result is 0 or 1 stored into a GPR
fmv.x.*, fmv.*.x	Move between the FP register and GPR, “*” is s or d
fcvt.*.l, fcvt.l.*., fcvt.*.lu, fcvt.lu.*., fcvt.*.w, fcvt.w.*., fcvt.*.wu, fcvt.wu.*	Converts between a FP register and integer register, where “*” is S or D for single or double precision. Signed and unsigned versions and word, doubleword versions

Figure A.28 A list of the vast majority of instructions in RV64G. This list can also be found on the back inside cover. This table omits system instructions, synchronization and atomic instructions, configuration instructions, instructions to reset and access performance counters, about 10 instructions in total.

Program	Loads	Stores	Branches	Jumps	ALU operations
astar	28%	6%	18%	2%	46%
bzip	20%	7%	11%	1%	54%
gcc	17%	23%	20%	4%	36%
gobmk	21%	12%	14%	2%	50%
h264ref	33%	14%	5%	2%	45%
hammer	28%	9%	17%	0%	46%
libquantum	16%	6%	29%	0%	48%
mcf	35%	11%	24%	1%	29%
omnetpp	23%	15%	17%	7%	31%
perlbench	25%	14%	15%	7%	39%
sjeng	19%	7%	15%	3%	56%
xalancbmk	30%	8%	27%	3%	31%

Figure A.29 RISC-V dynamic instruction mix for the SPECint2006 programs. Omnetpp includes 7% of the instructions that are floating point loads, stores, operations, or compares; no other program includes even 1% of other instruction types. A change in gcc in SPECint2006, creates an anomaly in behavior. Typical integer programs have load frequencies that are 1/5 to 3x the store frequency. In gcc, the store frequency is actually higher than the load frequency! This arises because a large fraction of the execution time is spent in a loop that clears memory by storing x0 (not where a compiler like gcc would usually spend most of its execution time!). A store instruction that stores a register pair, which some other RISC ISAs have included, would address this issue.

RISC-V Instruction Set Usage

To give an idea of which instructions are popular, [Figure A.29](#) shows the frequency of instructions and instruction classes for the SPECint2006 programs, using RV32G.

A.10

Fallacies and Pitfalls

Architects have repeatedly tripped on common, but erroneous, beliefs. In this section we look at a few of them.

Pitfall *Designing a “high-level” instruction set feature specifically oriented to supporting a high-level language structure.*

Attempts to incorporate high-level language features in the instruction set have led architects to provide powerful instructions with a wide range of flexibility. However, often these instructions do more work than is required in the frequent case, or they don’t exactly match the requirements of some languages. Many such efforts have been aimed at eliminating what in the 1970s was called the *semantic gap*. Although the idea is to supplement the instruction set with additions that bring

the hardware up to the level of the language, the additions can generate what Wulf et al. (1981) have called a *semantic clash*:

... by giving too much semantic content to the instruction, the computer designer made it possible to use the instruction only in limited contexts. [p. 43]

More often the instructions are simply overkill—they are too general for the most frequent case, resulting in unneeded work and a slower instruction. Again, the VAX CALLS is a good example. CALLS uses a callee save strategy (the registers to be saved are specified by the callee), *but* the saving is done by the call instruction in the caller. The CALLS instruction begins with the arguments pushed on the stack, and then takes the following steps:

1. Align the stack if needed.
2. Push the argument count on the stack.
3. Save the registers indicated by the procedure call mask on the stack (as mentioned in Section A.8). The mask is kept in the called procedure's code—this permits the callee to specify the registers to be saved by the caller even with separate compilation.
4. Push the return address on the stack, and then push the top and base of stack pointers (for the activation record).
5. Clear the condition codes, which sets the trap enable to a known state.
6. Push a word for status information and a zero word on the stack.
7. Update the two stack pointers.
8. Branch to the first instruction of the procedure.

The vast majority of calls in real programs do not require this amount of overhead. Most procedures know their argument counts, and a much faster linkage convention can be established using registers to pass arguments rather than the stack in memory. Furthermore, the CALLS instruction forces two registers to be used for linkage, while many languages require only one linkage register. Many attempts to support procedure call and activation stack management have failed to be useful, either because they do not match the language needs or because they are too general and hence too expensive to use.

The VAX designers provided a simpler instruction, JSB, that is much faster because it only pushes the return PC on the stack and jumps to the procedure. However, most VAX compilers use the more costly CALLS instructions. The call instructions were included in the architecture to standardize the procedure linkage convention. Other computers have standardized their calling convention by agreement among compiler writers and without requiring the overhead of a complex, very general procedure call instruction.

Fallacy *There is such a thing as a typical program.*

Figure A.30 Data reference size of four programs from SPEC2000. Although you can calculate an average size, it would be hard to claim the average is typical of programs.

Many people would like to believe that there is a single “typical” program that could be used to design an optimal instruction set. For example, see the synthetic benchmarks discussed in [Chapter 1](#). The data in this appendix clearly show that programs can vary significantly in how they use an instruction set. For example, [Figure A.30](#) shows the mix of data transfer sizes for four of the SPEC2000 programs: It would be hard to say what is typical from these four programs. The variations are even larger on an instruction set that supports a class of applications, such as decimal instructions, that are unused by other applications.

Pitfall *Innovating at the instruction set architecture to reduce code size without accounting for the compiler.*

[Figure A.31](#) shows the relative code sizes for four compilers for the MIPS instruction set. Whereas architects struggle to reduce code size by 30%–40%, different compiler strategies can change code size by much larger factors. Similar to performance optimization techniques, the architect should start with the tightest code the compilers can produce before proposing hardware innovations to save space.

Fallacy *An architecture with flaws cannot be successful.*

The 80x86 provides a dramatic example: the instruction set architecture is one only its creators could love (see Appendix K). Succeeding generations of Intel engineers have tried to correct unpopular architectural decisions made in designing the 80x86. For example, the 80x86 supports segmentation, whereas all others picked paging; it uses extended accumulators for integer data, but other processors use general-purpose registers; and it uses a stack for floating-point data, when everyone else abandoned execution stacks long before.

Compiler	Apogee software version 4.1	Green Hills Multi2000 Version 2.0	Algorithmics SDE4.0B	IDT/c 7.2.1
Architecture	MIPS IV	MIPS IV	MIPS 32	MIPS 32
Processor	NEC VR5432	NEC VR5000	IDT 32334	IDT 79RC32364
Autocorrelation kernel	1.0	2.1	1.1	2.7
Convolutional encoder kernel	1.0	1.9	1.2	2.4
Fixed-point bit allocation kernel	1.0	2.0	1.2	2.3
Fixed-point complex FFT kernel	1.0	1.1	2.7	1.8
Viterbi GSM decoder kernel	1.0	1.7	0.8	1.1
Geometric mean of five kernels	1.0	1.7	1.4	2.0

Figure A.31 Code size relative to Apogee Software Version 4.1 C compiler for Telecom application of EEMBC benchmarks. The instruction set architectures are virtually identical, yet the code sizes vary by factors of 2. These results were reported February–June 2000.

Despite these major difficulties, the 80x86 architecture has been enormously successful. The reasons are threefold: first, its selection as the microprocessor in the initial IBM PC makes 80x86 binary compatibility extremely valuable. Second, Moore’s Law provided sufficient resources for 80x86 microprocessors to translate to an internal RISC instruction set and then execute RISC-like instructions. This mix enables binary compatibility with the valuable PC software base and performance on par with RISC processors. Third, the very high volumes of PC microprocessors mean Intel can easily pay for the increased design cost of hardware translation. In addition, the high volumes allow the manufacturer to go up the learning curve, which lowers the cost of the product.

The larger die size and increased power for translation may be a liability for embedded applications, but it makes tremendous economic sense for the desktop. And its cost-performance in the desktop also makes it attractive for servers, with its main weakness for servers being 32-bit addresses, which was resolved with a 64-bit address extension.

Fallacy *You can design a flawless architecture.*

All architecture design involves trade-offs made in the context of a set of hardware and software technologies. Over time those technologies are likely to change, and decisions that may have been correct at the time they were made look like mistakes. For example, in 1975 the VAX designers overemphasized the importance of code size efficiency, underestimating how important ease of decoding and pipelining would be five years later. An example in the RISC camp is delayed branch (see Appendix K). It was a simple matter to control pipeline hazards with five-stage pipelines, but a challenge for processors with longer pipelines that issue multiple instructions per clock cycle. In addition, almost all architectures eventually succumb to the lack of sufficient address space. This is one reason that RISC-V

has planned for the possibility of 128-bit addresses, although it may be decades before such capability is needed.

In general, avoiding such flaws in the long run would probably mean compromising the efficiency of the architecture in the short run, which is dangerous, since a new instruction set architecture must struggle to survive its first few years.

A.11

Concluding Remarks

The earliest architectures were limited in their instruction sets by the hardware technology of that time. As soon as the hardware technology permitted, computer architects began looking for ways to support high-level languages. This search led to three distinct periods of thought about how to support programs efficiently. In the 1960s, stack architectures became popular. They were viewed as being a good match for high-level languages—and they probably were, given the compiler technology of the day. In the 1970s, the main concern of architects was how to reduce software costs. This concern was met primarily by replacing software with hardware, or by providing high-level architectures that could simplify the task of software designers. The result was both the high-level language computer architecture movement and powerful architectures like the VAX, which has a large number of addressing modes, multiple data types, and a highly orthogonal architecture. In the 1980s, more sophisticated compiler technology and a renewed emphasis on processor performance saw a return to simpler architectures, based mainly on the load-store style of computer.

The following instruction set architecture changes occurred in the 1990s:

- *Address size doubles*—The 32-bit address instruction sets for most desktop and server processors were extended to 64-bit addresses, expanding the width of the registers (among other things) to 64 bits. Appendix K gives three examples of architectures that have gone from 32 bits to 64 bits.
- *Optimization of conditional branches via conditional execution*—In [Chapter 3](#), we see that conditional branches can limit the performance of aggressive computer designs. Hence, there was interest in replacing conditional branches with conditional completion of operations, such as conditional move (see [Appendix H](#)), which was added to most instruction sets.
- *Optimization of cache performance via prefetch*—[Chapter 2](#) explains the increasing role of memory hierarchy in the performance of computers, with a cache miss on some computers taking as many instruction times as page faults took on earlier computers. Hence, prefetch instructions were added to try to hide the cost of cache misses by prefetching (see [Chapter 2](#)).
- *Support for multimedia*—Most desktop and embedded instruction sets were extended with support for multimedia applications.

- *Faster floating-point operations*—Appendix J describes operations added to enhance floating-point performance, such as operations that perform a multiply and an add and paired single execution, which are part of RISC-V.

Between 1970 and 1985 many thought the primary job of the computer architect was the design of instruction sets. As a result, textbooks of that era emphasize instruction set design, much as computer architecture textbooks of the 1950s and 1960s emphasized computer arithmetic. The educated architect was expected to have strong opinions about the strengths and especially the weaknesses of the popular computers. The importance of binary compatibility in quashing innovations in instruction set design was unappreciated by many researchers and textbook writers, giving the impression that many architects would get a chance to design an instruction set.

The definition of computer architecture today has been expanded to include design and evaluation of the full computer system—not just the definition of the instruction set and not just the processor—and hence there are plenty of topics for the architect to study. In fact, the material in this appendix was a central point of the book in its first edition in 1990, but now is included in an appendix primarily as reference material!

Appendix K may satisfy readers interested in instruction set architecture; it describes a variety of instruction sets, which are either important in the marketplace today or historically important, and it compares nine popular load-store computers with RISC-V.

A.12

Historical Perspective and References

Section M.4 (available online) features a discussion on the evolution of instruction sets and includes references for further reading and exploration of related topics.

Exercises by Gregory D. Peterson

- A.1 [10] < A.9 > Compute the effective CPI for an implementation of an embedded RISC-V CPU using Figure A.29. Assume we have made the following measurements of average CPI for each of the instruction types:

Instruction	Clock cycles
All ALU operations	1.0
Loads	5.0
Stores	3.0
Branches	
Taken	5.0
Not taken	3.0
Jumps	3.0

Average the instruction frequencies of `astar` and `gcc` to obtain the instruction mix.

- A.2 [10] < A.9 > Compute the effective CPI for RISC-V using Figure A.29 and the table above. Average the instruction frequencies of bzip and hmmer to obtain the instruction mix. You may assume that all other instructions (for instructions not accounted for by the types in Table A.29) require 3.0 clock cycles each.
- A.3 [10] < A.9 > Compute the effective CPI for an implementation of a RISC-V CPU using Figure A.29. Assume we have made the following measurements of average CPI for each of the instruction types:

Instruction	Clock cycles
All ALU operations	1.0
Loads	3.5
Stores	2.8
Branches	
Taken	4.0
Not taken	2.0
Jumps	2.4

Average the instruction frequencies of gobmk and mcf to obtain the instruction mix. You may assume that all other instructions (for instructions not accounted for by the types in Table A.29) require 3.0 clock cycles each.

- A.4 [10] < A.9 > Compute the effective CPI for RISC-V using Figure A.29 and the table above. Average the instruction frequencies of perlbench and sjeng to obtain the instruction mix.
- A.5 [10] < A.8 > Consider this high-level code sequence of three statements:
- ```
A = B + C ;
B = A + C ;
D = A - B ;
```

Use the technique of copy propagation (see Figure A.20) to transform the code sequence to the point where no operand is a computed value. Note the instances in which the transformation has reduced the computational work of a statement and those cases where the work has increased. What does this suggest about the technical challenge faced in trying to satisfy the desire for optimizing compilers?

- A.6 [30] < A.8 > Compiler optimizations may result in improvements to code size and/or performance. Consider one or more of the benchmark programs from the SPEC CPU2017 or the EEMBC benchmark suites. Use the RISC-V processor or a processor available to you along with the GNU C compiler to optimize the benchmark program(s) using no optimization, -O1, -O2, and -O3. Compare the performance and size of the resulting programs. Also compare your results to Figure A.21.

A.7 [20/20/20/25/10] < A.2, A.9 > Consider the following fragment of C code:

```
for (i=0; i<100; i++) {
 A[i]=B[i]+C;
}
```

Assume that A and B are arrays of 64-bit integers, and C and i are 64-bit integers. Assume that all data values and their addresses are kept in memory (at addresses 1000, 3000, 5000, and 7000 for A, B, C, and i, respectively) except when they are operated on. Assume that values in registers are lost between iterations of the loop. Assume all addresses and words are 64 bits.

- a. [20] < A.2, A.9 > Write the code for RISC-V. How many instructions are required dynamically? How many memory-data references will be executed? What is the code size in bytes?
- b. [20] < A.2 > Write the code for x86. How many instructions are required dynamically? How many memory-data references will be executed? What is the code size in bytes?
- c. [20] < A.2 > Write the code for a stack machine. Assume all operations occur on top of the stack. Push and pop are the only instructions that access memory; all others remove their operands from the stack and replace them with the result. The implementation uses a hardwired stack for only the top two stack entries, which keeps the processor circuit very small and low in cost. Additional stack positions are kept in memory locations, and accesses to these stack positions require memory references. How many instructions are required dynamically? How many memory-data references will be executed?
- d. [25] < A.2, A.9 > Instead of the code fragment above, write a routine for computing a matrix multiplication for dense, single precision matrices, also known as SGEMM. For input matrices of size  $100 \times 100$ , how many instructions are required dynamically? How many memory-data references will be executed?
- e. [10] < A.2, A.9 > As the matrix size increases, how does this affect the number of instructions executed dynamically or the number of memory-data references?

A.8 [25/25] < A.2, A.8, A.9 > Consider the following fragment of C code:

```
for(p=0; p<8; p++) {
 Y[p]=(9798*R[p]+19235*G[p]+3736*B[p])/32768;
 U[p]=(-4784*R[p]-9437*G[p]+4221*B[p])/32768+128;
 V[p]=(20218*R[p]-16941*G[p]-3277*B[p])/32768+128;
}
```

Assume that R, G, B, Y, U, and V are arrays of 64-bit integers. Assume that all data values and their addresses are kept in memory (at addresses 1000, 2000, 3000, 4000, 5000, and 6000 for R, G, B, Y, U, and V, respectively) except when they are operated on. Assume that values in registers are lost between iterations of the loop. Assume all addresses and words are 64 bits.

- a. [25] <A.2, A.9> Write the code for RISC-V. How many instructions are required dynamically? How many memory-data references will be executed? What is the code size in bytes?
  - b. [25] <A.2> Write the code for x86. How many instructions are required dynamically? How many memory-data references will be executed? What is the code size in bytes? Compare your results to the multimedia instructions (MMX) and vector implementations discussed in the A.8.
- A.9 [10/10/10/10] <A.2, A.7> For the following, we consider instruction encoding for instruction set architectures.
- a. [10] <A.2, A.7> Consider the case of a processor with an instruction length of 14 bits and with 64 general-purpose registers so the size of the address fields is 6 bits. Is it possible to have instruction encodings for the following?
    - 3 two-address instructions
    - 63 one-address instructions
    - 45 zero-address instructions
  - b. [10] <A.2, A.7> Assuming the same instruction length and address field sizes as above, determine if it is possible to have
    - 3 two-address instructions
    - 65 one-address instructions
    - 35 zero-address instructions

Explain your answer.

- c. [10] <A.2, A.7> Assume the same instruction length and address field sizes as above. Further assume there are already 3 two-address and 24 zero-address instructions. What is the maximum number of one-address instructions that can be encoded for this processor?
  - d. [10] <A.2, A.7> Assume the same instruction length and address field sizes as above. Further assume there are already 3 two-address and 65 zero-address instructions. What is the maximum number of one-address instructions that can be encoded for this processor?
- A.10 [10/15] <A.2> For the following assume that integer values A, B, C, D, E, and F reside in memory. Also assume that instruction operation codes are represented in 8 bits, memory addresses are 64 bits, and register addresses are 6 bits.
- a. [10] <A.2> For each instruction set architecture shown in Figure A.2, how many addresses, or names, appear in each instruction for the code to compute  $C = A + B$ , and what is the total code size?
  - b. [15] <A.2> Some of the instruction set architectures in Figure A.2 destroy operands in the course of computation. This loss of data values from processor internal storage has performance consequences. For each architecture in Figure A.2, write the code sequence to compute:
    - $C = A + B$
    - $D = A - E$
    - $F = C + D$

In your code, mark each operand that is destroyed during execution and mark each “overhead” instruction that is included just to overcome this loss of data from processor internal storage. What is the total code size, the number of bytes of instructions and data moved to or from memory, the number of overhead instructions, and the number of overhead data bytes for each of your code sequences?

- A.11 [15] <A.2, A.7, A.9> The design of RISC-V provides for 32 general-purpose registers and 32 floating-point registers. If registers are good, are more registers better? List and discuss as many trade-offs as you can that should be considered by instruction set architecture designers examining whether to, and how much to, increase the number of RISC-V registers.
- A.12 [5] <A.3> Consider a C struct that includes the following members:

```
struct foo {
 char a;
 bool b;
 int c;
 double d;
 short e;
 float f;
 double g;
 char *cptr;
 float *fptr;
 int x;
};
```

Note that for C, the compiler must keep the elements of the struct in the same order as given in the struct definition. For a 32-bit machine, what is the size of the foo struct? What is the minimum size required for this struct, assuming you may arrange the order of the struct members as you wish? What about for a 64-bit machine?

- A.13 [30] <A.7> Many computer manufacturers now include tools or simulators that allow you to measure the instruction set usage of a user program. Among the methods in use are machine simulation, hardware-supported trapping, and techniques that instrument the object code module by inserting counters in software or using built-in hardware counters. Pick a processor and tools to instrument user programs. (The open source RISC-V architecture supports a collection of tools. Tools such as the Performance API (PAPI) work with x86 processors.) Use the processor and tools to measure the instruction set mix for one of the SPEC CPU2017 benchmarks. Compare the results to those shown in this chapter.
- A.14 [30] <A.8> Newer processors such as Intel's i7 Kaby Lake include support for AVX2 vector/multimedia instructions. Write a dense matrix multiply function using single-precision values and compile it with different compilers and optimization flags. Linear algebra codes using Basic Linear Algebra Subroutine (BLAS) routines such as SGEMM include optimized versions of dense matrix multiply. Compare the code size and performance of your code to that of BLAS SGEMM. Explore what happens when using double-precision values and DGEMM.

- A.15 [30] < A.8 > For the SGEMM code developed above for the i7 processor, include the use of AVX2 intrinsics to improve the performance. In particular, try to vectorize your code to better utilize the AVX hardware. Compare the code size and performance to the original code. Compare your results to Intel's Math Kernel Library (MKL) implementation for SGEMM.
- A.16 [30] < A.7, A.9 > The RISC-V processor is open source and boasts an impressive collection of implementations, simulators, compilers, and other tools. See [riscv.org](http://riscv.org) for an overview of tools, including spike, a simulator for RISC-V processors. Use spike or another simulator to measure the instruction set mix for some SPEC CPU2017 benchmark programs.
- A.17 [35/35/35/35] < A.2–A.8 > gcc targets most modern instruction set architectures (see [www.gnu.org/software/gcc/](http://www.gnu.org/software/gcc/)). Create a version of gcc for several architectures that you have access to, such as x86, RISC-V, PowerPC, and ARM.
- [35] < A.2–A.8 > Compile a subset of SPEC CPU2017 integer benchmarks and create a table of code sizes. Which architecture is best for each program?
  - [35] < A.2–A.8 > Compile a subset of SPEC CPU2017 floating-point benchmarks and create a table of code sizes. Which architecture is best for each program?
  - [35] < A.2–A.8 > Compile a subset of EEMBC AutoBench benchmarks (see [www.eembc.org/home.php](http://www.eembc.org/home.php)) and create a table of code sizes. Which architecture is best for each program?
  - [35] < A.2–A.8 > Compile a subset of EEMBC FPBench floating-point benchmarks and create a table of code sizes. Which architecture is best for each program?
- A.18 [40] < A.2–A.8 > Power efficiency has become very important for modern processors, particularly for embedded systems. Create a version of gcc for two architectures that you have access to, such as x86, RISC-V, PowerPC, Atom, and ARM. (Note that the different versions of RISC-V can also be explored and compared.) Compile a subset of EEMBC benchmarks while using EnergyBench to measure energy usage during execution. Compare code size, performance, and energy usage for the processors. Which is best for each program?
- A.19 [20/15/15/20] Your task is to compare the memory efficiency of four different styles of instruction set architectures. The architecture styles are:
- *Accumulator*—All operations occur between a single register and a memory location.
  - *Memory-memory*—All instruction addresses reference only memory locations.
  - *Stack*—All operations occur on top of the stack. Push and pop are the only instructions that access memory; all others remove their operands from the stack and replace them with the result. The implementation uses a hardwired stack for only the top two stack entries, which keeps the processor circuit very small and low in cost. Additional stack positions are kept in memory locations, and accesses to these stack positions require memory references.

- *Load-store*—All operations occur in registers, and register-to-register instructions have three register names per instruction.

To measure memory efficiency, make the following assumptions about all four instruction sets:

- All instructions are an integral number of bytes in length.
  - The opcode is always one byte (8 bits).
  - Memory accesses use direct, or absolute, addressing.
  - The variables A, B, C, and D are initially in memory.
- [20] <A.2, A.3> Invent your own assembly language mnemonics (Figure A.2 provides a useful sample to generalize), and for each architecture write the best equivalent assembly language code for this high-level language code sequence:
 

```
A = B + C ;
B = A + C ;
D = A - B ;
```
  - [15] <A.3> Label each instance in your assembly codes for part (a) where a value is loaded from memory after having been loaded once. Also label each instance in your code where the result of one instruction is passed to another instruction as an operand, and further classify these events as involving storage within the processor or storage in memory.
  - [15] <A.7> Assume that the given code sequence is from a small, embedded computer application that uses a 16-bit memory address and data operands. If a load-store architecture is used, assume it has 16 general-purpose registers. For each architecture answer the following questions: How many instruction bytes are fetched? How many bytes of data are transferred from/to memory? Which architecture is most efficient as measured by total memory traffic (code + data)?
  - [20] <A.7> Now assume a processor with 64-bit memory addresses and data operands. For each architecture answer the questions of part (c). How have the relative merits of the architectures changed for the chosen metrics?

- A.20 [30] <A.2, A.3> Use the four different instruction set architecture styles from above, but assume that the memory operations supported include register indirect as well as direct addressing. Invent your own assembly language mnemonics (Figure A.2 provides a useful sample to generalize), and for each architecture, write the best equivalent assembly language code for this fragment of C code:

```
for (i = 0; i <= 100; i++) {
 A[i] = B[i] * C + D ;
}
```

Assume that A and B are arrays of 64-bit integers, and C, D, and i are 64-bit integers.

- A.21 [20/20] < A.3, A.6, A.9 > The size of displacement values needed for the displacement addressing mode or for PC-relative addressing can be extracted from compiled applications. Use a disassembler with one or more of the SPEC CPU2017 or EEMBC benchmarks compiled for the RISC-V processor.
- [20] < A.3, A.9 > For each instruction using displacement addressing, record the displacement value used. Create a histogram of displacement values. Compare the results to those shown in this appendix in Figure A.8.
  - [20] < A.6, A.9 > For each branch instruction using PC-relative addressing, record the offset value used. Create a histogram of offset values. Compare the results to those shown in this chapter in Figure A.15.
- A.22 [15/15/10/10/10/10] < A.3 > The value represented by the hexadecimal number 5249 5343 5643 5055 is to be stored in an aligned 64-bit double word.
- [15] < A.3 > Using the physical arrangement of the first row in Figure A.5, write the value to be stored using Big Endian byte order. Next, interpret each byte as an ASCII character and below each byte write the corresponding character, forming the character string as it would be stored in Big Endian order.
  - [15] < A.3 > Using the same physical arrangement as in part (a), write the value to be stored using Little Endian byte order, and below each byte write the corresponding ASCII character.
  - [10] < A.3 > What are the hexadecimal values of all misaligned 2-byte words that can be read from the given 64-bit double word when stored in Big Endian byte order?
  - [10] < A.3 > What are the hexadecimal values of all misaligned 2-byte words that can be read from the given 64-bit double word when stored in Big Endian byte order?
  - [10] < A.3 > What are the hexadecimal values of all misaligned 2-byte words that can be read from the given 64-bit double word when stored in Little Endian byte order?
  - [10] < A.3 > What are the hexadecimal values of all misaligned 4-byte words that can be read from the given 64-bit double word when stored in Little Endian byte order?
- A.23 [25,25] < A.3, A.9 > The relative frequency of different addressing modes impacts the choices of addressing modes support for an instruction set architecture. Figure A.7 illustrates the relative frequency of addressing modes for three applications on the VAX.
- [25] < A.3 > Compile one or more programs from the SPEC CPU2017 or EEMBC benchmark suites to target the x86 architecture. Using a disassembler, inspect the instructions and the relative frequency of various addressing modes. Create a histogram to illustrate the relative frequency of the addressing modes. How do your results compare to Figure A.7?

- b. [25] < A.3, A.9 > Compile one or more programs from the SPEC CPU2017 or EEMBC benchmark suites to target the RISC-V architecture. Using a disassembler, inspect the instructions and the relative frequency of various addressing modes. Create a histogram to illustrate the relative frequency of the addressing modes. How do your results compare to Figure A.7?
- A.24 [Discussion] < A.2–A.12 > Consider typical applications for desktop, server, cloud, and embedded computing. How would instruction set architecture be impacted for machines targeting each of these markets?

## Review of Memory Hierarchy

Cache: a safe place for hiding or storing things.

**Webster's New World Dictionary of  
the American Language,**  
Second College Edition (1976)

B.1 Introduction

This appendix is a quick refresher of the memory hierarchy, including the basics of cache and virtual memory, performance equations, and simple optimizations. This first section reviews the following 36 terms:

|                                   |                              |                               |
|-----------------------------------|------------------------------|-------------------------------|
| <i>cache</i>                      | <i>fully associative</i>     | <i>write allocate</i>         |
| <i>virtual memory</i>             | <i>dirty bit</i>             | <i>unified cache</i>          |
| <i>memory stall cycles</i>        | <i>block offset</i>          | <i>misses per instruction</i> |
| <i>direct mapped</i>              | <i>write back</i>            | <i>block</i>                  |
| <i>valid bit</i>                  | <i>data cache</i>            | <i>locality</i>               |
| <i>block address</i>              | <i>hit time</i>              | <i>address trace</i>          |
| <i>write through</i>              | <i>cache miss</i>            | <i>set</i>                    |
| <i>instruction cache</i>          | <i>page fault</i>            | <i>random replacement</i>     |
| <i>average memory access time</i> | <i>miss rate</i>             | <i>index field</i>            |
| <i>cache hit</i>                  | <i>n-way set associative</i> | <i>no-write allocate</i>      |
| <i>page</i>                       | <i>least recently used</i>   | <i>write buffer</i>           |
| <i>miss penalty</i>               | <i>tag field</i>             | <i>write stall</i>            |

If this review goes too quickly, you might want to look at [Chapter 7](#) in *Computer Organization and Design*, which we wrote for readers with less experience.

*Cache* is the name given to the highest or first level of the memory hierarchy encountered once the address leaves the processor. Because the principle of locality applies at many levels, and taking advantage of locality to improve performance is popular, the term *cache* is now applied whenever buffering is employed to reuse commonly occurring items. Examples include *file caches*, *name caches*, and so on.

When the processor finds a requested data item in the cache, it is called a *cache hit*. When the processor does not find a data item it needs in the cache, a *cache miss* occurs. A fixed-size collection of data containing the requested word, called a *block* or line run, is retrieved from the main memory and placed into the cache. *Temporal locality* tells us that we are likely to need this word again in the near future, so it is useful to place it in the cache where it can be accessed quickly. Because of *spatial locality*, there is a high probability that the other data in the block will be needed soon.

The time required for the cache miss depends on both the latency and bandwidth of the memory. Latency determines the time to retrieve the first word of the block, and bandwidth determines the time to retrieve the rest of this block. A cache miss is handled by hardware and causes processors using in-order execution to pause, or stall, until the data are available. With out-of-order execution, an instruction using the result must still wait, but other instructions may proceed during the miss.

Similarly, not all objects referenced by a program need to reside in main memory. *Virtual memory* means some objects may reside on disk. The address space is

| Level                     | 1                                       | 2                 | 3                | 4                      |
|---------------------------|-----------------------------------------|-------------------|------------------|------------------------|
| Name                      | Registers                               | Cache             | Main memory      | Disk storage           |
| Typical size              | <4 KiB                                  | 32 KiB to 8 MiB   | <1 TB            | >1 TB                  |
| Implementation technology | Custom memory with multiple ports, CMOS | On-chip CMOS SRAM | CMOS DRAM        | Magnetic disk or FLASH |
| Access time (ns)          | 0.1–0.2                                 | 0.5–10            | 30–150           | 5,000,000              |
| Bandwidth (MiB/sec)       | 1,000,000–10,000,000                    | 20,000–50,000     | 10,000–30,000    | 100–1000               |
| Managed by                | Compiler                                | Hardware          | Operating system | Operating system       |
| Backed by                 | Cache                                   | Main memory       | Disk or FLASH    | Other disks and DVD    |

**Figure B.1** The typical levels in the hierarchy slow down and get larger as we move away from the processor for a large workstation or small server. Embedded computers might have no disk storage and much smaller memories and caches. Increasingly, FLASH is replacing magnetic disks, at least for first level file storage. The access times increase as we move to lower levels of the hierarchy, which makes it feasible to manage the transfer less responsively. The implementation technology shows the typical technology used for these functions. The access time is given in nanoseconds for typical values in 2017; these times will decrease over time. Bandwidth is given in megabytes per second between levels in the memory hierarchy. Bandwidth for disk/FLASH storage includes both the media and the buffered interfaces.

usually broken into fixed-size blocks, called *pages*. At any time, each page resides either in main memory or on disk. When the processor references an item within a page that is not present in the cache or main memory, a *palt* occurs, and the entire page is moved from the disk to main memory. Because page faults take so long, they are handled in software and the processor is not stalled. The processor usually switches to some other task while the disk access occurs. From a high-level perspective, the reliance on locality of references and the relative relationships in size and relative cost per bit of cache versus main memory are similar to those of main memory versus disk.

Figure B.1 shows the range of sizes and access times of each level in the memory hierarchy for computers ranging from high-end desktops to low-end servers.

## Cache Performance Review

Because of locality and the higher speed of smaller memories, a memory hierarchy can substantially improve performance. One method to evaluate cache performance is to expand our processor execution time equation from Chapter 1. We now account for the number of cycles during which the processor is stalled waiting for a memory access, which we call the *memory stall cycles*. The performance is then the product of the clock cycle time and the sum of the processor cycles and the memory stall cycles:

$$\text{CPU execution time} = (\text{CPU clock cycles} + \text{Memory stall cycles}) \times \text{Clock cycle time}$$

This equation assumes that the CPU clock cycles include the time to handle a cache hit and that the processor is stalled during a cache miss. [Section B.2](#) reexamines this simplifying assumption.

The number of memory stall cycles depends on both the number of misses and the cost per miss, which is called the *miss penalty*:

$$\begin{aligned}\text{Memory stall cycles} &= \text{Number of misses} \times \text{Miss penalty} \\ &= \text{IC} \times \frac{\text{Misses}}{\text{Instruction}} \times \text{Miss penalty} \\ &= \text{IC} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss rate} \times \text{Miss penalty}\end{aligned}$$

The advantage of the last form is that the components can be easily measured. We already know how to measure instruction count (IC). (For speculative processors, we only count instructions that commit.) Measuring the number of memory references per instruction can be done in the same fashion; every instruction requires an instruction access, and it is easy to decide if it also requires a data access.

Note that we calculated miss penalty as an average, but we will use it herein as if it were a constant. The memory behind the cache may be busy at the time of the miss because of prior memory requests or memory refresh. The number of clock cycles also varies at interfaces between different clocks of the processor, bus, and memory. Thus, please remember that using a single number for miss penalty is a simplification.

The component *miss rate* is simply the fraction of cache accesses that result in a miss (i.e., number of accesses that miss divided by number of accesses). Miss rates can be measured with cache simulators that take an *address trace* of the instruction and data references, simulate the cache behavior to determine which references hit and which miss, and then report the hit and miss totals. Many microprocessors today provide hardware to count the number of misses and memory references, which is a much easier and faster way to measure miss rate.

The preceding formula is an approximation because the miss rates and miss penalties are often different for reads and writes. Memory stall clock cycles could then be defined in terms of the number of memory accesses per instruction, miss penalty (in clock cycles) for reads and writes, and miss rate for reads and writes:

$$\begin{aligned}\text{Memory stall clock cycles} &= \text{IC} \times \text{Reads per instruction} \times \text{Read miss rate} \times \text{Read miss penalty} \\ &\quad + \text{IC} \times \text{Writes per instruction} \times \text{Write miss rate} \times \text{Write miss penalty}\end{aligned}$$

We usually simplify the complete formula by combining the reads and writes and finding the average miss rates and miss penalty for reads *and* writes:

$$\text{Memory stall clock cycles} = \text{IC} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss rate} \times \text{Miss penalty}$$

The miss rate is one of the most important measures of cache design, but, as we will see in later sections, not the only measure.

**Example** Assume we have a computer where the cycles per instruction (CPI) is 1.0 when all memory accesses hit in the cache. The only data accesses are loads and stores, and these total 50% of the instructions. If the miss penalty is 50 clock cycles and the miss rate is 1%, how much faster would the computer be if all instructions were cache hits?

**Answer** First compute the performance for the computer that always hits:

$$\begin{aligned}\text{CPU execution time} &= (\text{CPU clock cycles} + \text{Memory stall cycles}) \times \text{Clock cycle} \\ &= (\text{IC} \times \text{CPI} + 0) \times \text{Clock cycle} \\ &= \text{IC} \times 1.0 \times \text{Clock cycle}\end{aligned}$$

Now for the computer with the real cache, first we compute memory stall cycles:

$$\begin{aligned}\text{Memory stall cycles} &= \text{IC} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss rate} \times \text{Miss penalty} \\ &= \text{IC} \times (1 + 0.5) \times 0.01 \times 50 \\ &= \text{IC} \times 0.75\end{aligned}$$

where the middle term  $(1 + 0.5)$  represents one instruction access and 0.5 data accesses per instruction. The total performance is thus

$$\begin{aligned}\text{CPU execution time}_{\text{cache}} &= (\text{IC} \times 1.0 + \text{IC} \times 0.75) \times \text{Clock cycle} \\ &= 1.75 \times \text{IC} \times \text{Clock cycle}\end{aligned}$$

The performance ratio is the inverse of the execution times:

$$\begin{aligned}\frac{\text{CPU execution time}_{\text{cache}}}{\text{CPU execution time}} &= \frac{1.75 \times \text{IC} \times \text{Clock cycle}}{1.0 \times \text{IC} \times \text{Clock cycle}} \\ &= 1.75\end{aligned}$$

The computer with no cache misses is 1.75 times faster.

Some designers prefer measuring miss rate as *misses per instruction* rather than misses per memory reference. These two are related:

$$\frac{\text{Misses}}{\text{Instruction}} = \frac{\text{Miss rate} \times \text{Memory accesses}}{\text{Instruction count}} = \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}}$$

The latter formula is useful when you know the average number of memory accesses per instruction because it allows you to convert miss rate into misses per instruction, and vice versa. For example, we can turn the miss rate per memory reference in the previous example into misses per instruction:

$$\frac{\text{Misses}}{\text{Instruction}} = \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}} = 0.02 \times (1.5) = 0.030$$

By the way, misses per instruction are often reported as misses per 1000 instructions to show integers instead of fractions. Thus, the preceding answer could also be expressed as 30 misses per 1000 instructions.

The advantage of misses per instruction is that it is independent of the hardware implementation. For example, speculative processors fetch about twice as many instructions as are actually committed, which can artificially reduce the miss rate if measured as misses per memory reference rather than per instruction. The drawback is that misses per instruction is architecture dependent; for example, the average number of memory accesses per instruction may be very different for an 80x86 versus RISC V. Thus, misses per instruction are most popular with architects working with a single computer family, although the similarity of RISC architectures allows one to give insights into others.

---

**Example** To show equivalency between the two miss rate equations, let's redo the preceding example, this time assuming a miss rate per 1000 instructions of 30. What is memory stall time in terms of instruction count?

**Answer** Recomputing the memory stall cycles:

$$\begin{aligned}
 \text{Memory stall cycles} &= \text{Number of misses} \times \text{Miss penalty} \\
 &= \text{IC} \times \frac{\text{Misses}}{\text{Instruction}} \times \text{Miss penalty} \\
 &= \text{IC}/1000 \times \frac{\text{Misses}}{\text{Instruction} \times 1000} \times \text{Miss penalty} \\
 &= \text{IC}/1000 \times 30 \times 25 \\
 &= \text{IC}/1000 \times 750 \\
 &= \text{IC} \times 0.75
 \end{aligned}$$

We get the same answer as on page B-5, showing equivalence of the two equations.

---

## Four Memory Hierarchy Questions

We continue our introduction to caches by answering the four common questions for the first level of the memory hierarchy:

- Q1: Where can a block be placed in the upper level? (*block placement*)
- Q2: How is a block found if it is in the upper level? (*block identification*)
- Q3: Which block should be replaced on a miss? (*block replacement*)
- Q4: What happens on a write? (*write strategy*)

The answers to these questions help us understand the different trade-offs of memories at different levels of a hierarchy; hence, we ask these four questions on every example.

### Q1: Where Can a Block be Placed in a Cache?

Figure B.2 shows that the restrictions on where a block is placed create three categories of cache organization:

- If each block has only one place it can appear in the cache, the cache is said to be *direct mapped*. The mapping is usually  

$$(\text{Block address}) \bmod (\text{Number of blocks in cache})$$
- If a block can be placed anywhere in the cache, the cache is said to be *fully associative*.

**Figure B.2** This example cache has eight block frames and memory has 32 blocks. The three options for caches are shown left to right. In fully associative, block 12 from the lower level can go into any of the eight block frames of the cache. With direct mapped, block 12 can only be placed into block frame 4 ( $12 \bmod 8$ ). Set associative, which has some of both features, allows the block to be placed anywhere in set 0 ( $12 \bmod 4$ ). With two blocks per set, this means block 12 can be placed either in block 0 or in block 1 of the cache. Real caches contain thousands of block frames, and real memories contain millions of blocks. The set associative organization has four sets with two blocks per set, called *two-way set associative*. Assume that there is nothing in the cache and that the block address in question identifies lower-level block 12.

- If a block can be placed in a restricted set of places in the cache, the cache is *set associative*. A *set* is a group of blocks in the cache. A block is first mapped onto a set, and then the block can be placed anywhere within that set. The set is usually chosen by *bit selection*; that is,

$$(Block\ address) \bmod (Number\ of\ sets\ in\ cache)$$

If there are  $n$  blocks in a set, the cache placement is called *n-way set associative*.

The range of caches from direct mapped to fully associative is really a continuum of levels of set associativity. Direct mapped is simply one-way set associative, and a fully associative cache with  $m$  blocks could be called “ $m$ -way set associative.” Equivalently, direct mapped can be thought of as having  $m$  sets, and fully associative as having one set.

The vast majority of processor caches today are direct mapped, two-way set associative, or four-way set associative, for reasons we will see shortly.

*Q2: How Is a Block Found If It Is in the Cache?*

Caches have an address tag on each block frame that gives the block address. The tag of every cache block that might contain the desired information is checked to see if it matches the block address from the processor. As a rule, all possible tags are searched in parallel because speed is critical.

There must be a way to know that a cache block does not have valid information. The most common procedure is to add a *valid bit* to the tag to say whether or not this entry contains a valid address. If the bit is not set, there cannot be a match on this address.

Before proceeding to the next question, let’s explore the relationship of a processor address to the cache. Figure B.3 shows how an address is divided. The first division is between the *block address* and the *block offset*. The block frame address can be further divided into the *tag field* and the *index field*. The block offset field selects the desired data from the block, the index field selects the set, and the tag field is compared against it for a hit. Although the comparison could be made on more of the address than the tag, there is no need because of the following:

- The offset should not be used in the comparison, because the entire block is present or not, and hence all block offsets result in a match by definition.

**Figure B.3** The three portions of an address in a set associative or direct-mapped cache. The tag is used to check all the blocks in the set, and the index is used to select the set. The block offset is the address of the desired data within the block. Fully associative caches have no index field.

- Checking the index is redundant, because it was used to select the set to be checked. An address stored in set 0, for example, must have 0 in the index field or it couldn't be stored in set 0; set 1 must have an index value of 1; and so on. This optimization saves hardware and power by reducing the width of memory size for the cache tag.

If the total cache size is kept the same, increasing associativity increases the number of blocks per set, thereby decreasing the size of the index and increasing the size of the tag. That is, the tag-index boundary in [Figure B.3](#) moves to the right with increasing associativity, with the end point of fully associative caches having no index field.

### *Q3: Which Block Should be Replaced on a Cache Miss?*

When a miss occurs, the cache controller must select a block to be replaced with the desired data. A benefit of direct-mapped placement is that hardware decisions are simplified—in fact, so simple that there is no choice: only one block frame is checked for a hit, and only that block can be replaced. With fully associative or set associative placement, there are many blocks to choose from on a miss. There are three primary strategies employed for selecting which block to replace:

- *Random*—To spread allocation uniformly, candidate blocks are randomly selected. Some systems generate pseudorandom block numbers to get reproducible behavior, which is particularly useful when debugging hardware.
- *Least recently used (LRU)*—To reduce the chance of throwing out information that will be needed soon, accesses to blocks are recorded. Relying on the past to predict the future, the block replaced is the one that has been unused for the longest time. LRU relies on a corollary of locality: if recently used blocks are likely to be used again, then a good candidate for disposal is the least recently used block.
- *First in, first out (FIFO)*—Because LRU can be complicated to calculate, this approximates LRU by determining the *oldest* block rather than the LRU.

A virtue of random replacement is that it is simple to build in hardware. As the number of blocks to keep track of increases, LRU becomes increasingly expensive and is usually only approximated. A common approximation (often called pseudo-LRU) has a set of bits for each set in the cache with each bit corresponding to a single way (a *way* is bank in a set associative cache; there are four ways in four-way set associative cache) in the cache. When a set is accessed, the bit corresponding to the way containing the desired block is turned on; if all the bits associated with a set are turned on, they are reset with the exception of the most recently turned on bit. When a block must be replaced, the processor chooses a block from the way whose bit is turned off, often randomly if more than one choice is available. This approximates LRU, because the block that is replaced will not have

| Size    | Associativity |        |       |          |        |       |           |        |       |
|---------|---------------|--------|-------|----------|--------|-------|-----------|--------|-------|
|         | Two-way       |        |       | Four-way |        |       | Eight-way |        |       |
|         | LRU           | Random | FIFO  | LRU      | Random | FIFO  | LRU       | Random | FIFO  |
| 16 KiB  | 114.1         | 117.3  | 115.5 | 111.7    | 115.1  | 113.3 | 109.0     | 111.8  | 110.4 |
| 64 KiB  | 103.4         | 104.3  | 103.9 | 102.4    | 102.3  | 103.1 | 99.7      | 100.5  | 100.3 |
| 256 KiB | 92.2          | 92.1   | 92.5  | 92.1     | 92.1   | 92.5  | 92.1      | 92.1   | 92.5  |

**Figure B.4** Data cache misses per 1000 instructions comparing least recently used, random, and first in, first out replacement for several sizes and associativities. There is little difference between LRU and random for the largest size cache, with LRU outperforming the others for smaller caches. FIFO generally outperforms random in the smaller cache sizes. These data were collected for a block size of 64 bytes for the Alpha architecture using 10 SPEC2000 benchmarks. Five are from SPECint2000 (gap, gcc, gzip, mcf, and perl) and five are from SPECfp2000 (applu, art, equake, lucas, and swim). We will use this computer and these benchmarks in most figures in this appendix.

been accessed since the last time that all the blocks in the set were accessed. [Figure B.4](#) shows the difference in miss rates between LRU, random, and FIFO replacement.

*Q4: What Happens on a Write?*

Reads dominate processor cache accesses. All instruction accesses are reads, and most instructions don’t write to memory. Figures A.32 and A.33 in [Appendix A](#) suggest a mix of 10% stores and 26% loads for RISC V programs, making writes 10%/(100% + 26% + 10%) or about 7% of the overall memory traffic. Of the *data cache* traffic, writes are 10%/(26% + 10%) or about 28%. Making the common case fast means optimizing caches for reads, especially because processors traditionally wait for reads to complete but need not wait for writes. Amdahl’s Law (Section 1.9) reminds us, however, that high-performance designs cannot neglect the speed of writes.

Fortunately, the common case is also the easy case to make fast. The block can be read from the cache at the same time that the tag is read and compared, so the block read begins as soon as the block address is available. If the read is a hit, the requested part of the block is passed on to the processor immediately. If it is a miss, there is no benefit—but also no harm except more power in desktop and server computers; just ignore the value read.

Such optimism is not allowed for writes. Modifying a block cannot begin until the tag is checked to see if the address is a hit. Because tag checking cannot occur in parallel, writes usually take longer than reads. Another complexity is that the processor also specifies the size of the write, usually between 1 and 8 bytes; only that portion of a block can be changed. In contrast, reads can access more bytes than necessary without fear.

The write policies often distinguish cache designs. There are two basic options when writing to the cache:

- *Write through*—The information is written to both the block in the cache *and* to the block in the lower-level memory.
- *Write back*—The information is written only to the block in the cache. The modified cache block is written to main memory only when it is replaced.

To reduce the frequency of writing back blocks on replacement, a feature called the *dirty bit* is commonly used. This status bit indicates whether the block is *dirty* (modified while in the cache) or *clean* (not modified). If it is clean, the block is not written back on a miss, because identical information to the cache is found in lower levels.

Both write back and write through have their advantages. With write back, writes occur at the speed of the cache memory, and multiple writes within a block require only one write to the lower-level memory. Because some writes don't go to memory, write back uses less memory bandwidth, making write back attractive in multiprocessors. Since write back uses the rest of the memory hierarchy and memory interconnect less than write through, it also saves power, making it attractive for embedded applications.

Write through is easier to implement than write back. The cache is always clean, so unlike write back read misses never result in writes to the lower level. Write through also has the advantage that the next lower level has the most current copy of the data, which simplifies data coherency. Data coherency is important for multiprocessors and for I/O, which we examine in [Chapter 4](#) and Appendix D. Multilevel caches make write through more viable for the upper-level caches, as the writes need only propagate to the next lower level rather than all the way to main memory.

As we will see, I/O and multiprocessors are fickle: they want write back for processor caches to reduce the memory traffic and write through to keep the cache consistent with lower levels of the memory hierarchy.

When the processor must wait for writes to complete during write through, the processor is said to *write stall*. A common optimization to reduce write stalls is a *write buffer*, which allows the processor to continue as soon as the data are written to the buffer, thereby overlapping processor execution with memory updating. As we will see shortly, write stalls can occur even with write buffers.

Because the data are not needed on a write, there are two options on a write miss:

- *Write allocate*—The block is allocated on a write miss, followed by the preceding write hit actions. In this natural option, write misses act like read misses.
- *No-write allocate*—This apparently unusual alternative is write misses do *not* affect the cache. Instead, the block is modified only in the lower-level memory.

Thus, blocks stay out of the cache in no-write allocate until the program tries to read the blocks, but even blocks that are only written will still be in the cache with write allocate. Let's look at an example.

---

**Example** Assume a fully associative write-back cache with many cache entries that starts empty. Following is a sequence of five memory operations (the address is in square brackets):

```
Write Mem[100];
Write Mem[100];
Read Mem[200];
Write Mem[200];
Write Mem[100].
```

What are the number of hits and misses when using no-write allocate versus write allocate?

**Answer** For no-write allocate, the address 100 is not in the cache, and there is no allocation on write, so the first two writes will result in misses. Address 200 is also not in the cache, so the read is also a miss. The subsequent write to address 200 is a hit. The last write to 100 is still a miss. The result for no-write allocate is four misses and one hit.

For write allocate, the first accesses to 100 and 200 are misses, and the rest are hits because 100 and 200 are both found in the cache. Thus, the result for write allocate is two misses and three hits.

---

Either write miss policy could be used with write through or write back. Usually, write-back caches use write allocate, hoping that subsequent writes to that block will be captured by the cache. Write-through caches often use no-write allocate. The reasoning is that even if there are subsequent writes to that block, the writes must still go to the lower-level memory, so what's to be gained?

## An Example: The Opteron Data Cache

To give substance to these ideas, [Figure B.5](#) shows the organization of the data cache in the AMD Opteron microprocessor. The cache contains 65,536 (64 K) bytes of data in 64-byte blocks with two-way set associative placement, least-recently used replacement, write back, and write allocate on a write miss.

Let's trace a cache hit through the steps of a hit as labeled in [Figure B.5](#). (The four steps are shown as circled numbers.) As described in [Section B.5](#), the Opteron presents a 48-bit virtual address to the cache for tag comparison, which is simultaneously translated into a 40-bit physical address.

The reason Opteron doesn't use all 64 bits of virtual address is that its designers don't think anyone needs that much virtual address space yet, and the smaller size simplifies the Opteron virtual address mapping. The designers plan to grow the virtual address in future microprocessors.

The physical address coming into the cache is divided into two fields: the 34-bit block address and the 6-bit block offset ( $64 = 2^6$  and  $34 + 6 = 40$ ). The block

**Figure B.5** The organization of the data cache in the Opteron microprocessor. The 64 KiB cache is two-way set associative with 64-byte blocks. The 9-bit index selects among 512 sets. The four steps of a read hit, shown as circled numbers in order of occurrence, label this organization. Three bits of the block offset join the index to supply the RAM address to select the proper 8 bytes. Thus, the cache holds two groups of 4096 64-bit words, with each group containing half of the 512 sets. Although not exercised in this example, the line from lower-level memory to the cache is used on a miss to load the cache. The size of address leaving the processor is 40 bits because it is a physical address and not a virtual address. [Figure B.24](#) on page B-47 explains how the Opteron maps from virtual to physical for a cache access.

address is further divided into an address tag and cache index. Step 1 shows this division.

The cache index selects the tag to be tested to see if the desired block is in the cache. The size of the index depends on cache size, block size, and set associativity. For the Opteron cache the set associativity is set to two, and we calculate the index as follows:

$$2^{\text{Index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}} = \frac{65,536}{64 \times 2} = 512 = 2^9$$

Hence, the index is 9 bits wide, and the tag is  $34 - 9$  or 25 bits wide. Although that is the index needed to select the proper block, 64 bytes is much more than the processor wants to consume at once. Hence, it makes more sense to organize the data portion of the cache memory 8 bytes wide, which is the natural data word of the 64-bit Opteron processor. Thus, in addition to 9 bits to index the proper cache block, 3 more bits from the block offset are used to index the proper 8 bytes. Index selection is step 2 in [Figure B.5](#).

After reading the two tags from the cache, they are compared with the tag portion of the block address from the processor. This comparison is step 3 in the figure. To be sure the tag contains valid information, the valid bit must be set or else the results of the comparison are ignored.

Assuming one tag does match, the final step is to signal the processor to load the proper data from the cache by using the winning input from a 2:1 multiplexor. The Opteron allows 2 clock cycles for these four steps, so the instructions in the following 2 clock cycles would wait if they tried to use the result of the load.

Handling writes is more complicated than handling reads in the Opteron, as it is in any cache. If the word to be written is in the cache, the first three steps are the same. Because the Opteron executes out of order, only after it signals that the instruction has committed and the cache tag comparison indicates a hit are the data written to the cache.

So far we have assumed the common case of a cache hit. What happens on a miss? On a read miss, the cache sends a signal to the processor telling it the data are not yet available, and 64 bytes are read from the next level of the hierarchy. The latency is 7 clock cycles to the first 8 bytes of the block, and then 2 clock cycles per 8 bytes for the rest of the block. Because the data cache is set associative, there is a choice on which block to replace. Opteron uses LRU, which selects the block that was referenced longest ago, so every access must update the LRU bit. Replacing a block means updating the data, the address tag, the valid bit, and the LRU bit.

Because the Opteron uses write back, the old data block could have been modified, and hence it cannot simply be discarded. The Opteron keeps 1 dirty bit per block to record if the block was written. If the “victim” was modified, its data and address are sent to the victim buffer. (This structure is similar to a *write buffer* in other computers.) The Opteron has space for eight victim blocks. In parallel with other cache actions, it writes victim blocks to the next level of the hierarchy. If the victim buffer is full, the cache must wait.

A write miss is very similar to a read miss, because the Opteron allocates a block on a read or a write miss.

We have seen how it works, but the *data* cache cannot supply all the memory needs of the processor: the processor also needs instructions. Although a single cache could try to supply both, it can be a bottleneck. For example, when a load or store instruction is executed, the pipelined processor will simultaneously request both a data word *and* an instruction word. Hence, a single cache would present a structural hazard for loads and stores, leading to stalls. One simple way to conquer

| Size (KiB) | Instruction cache | Data cache | Unified cache |
|------------|-------------------|------------|---------------|
| 8          | 8.16              | 44.0       | 63.0          |
| 16         | 3.82              | 40.9       | 51.0          |
| 32         | 1.36              | 38.4       | 43.3          |
| 64         | 0.61              | 36.9       | 39.4          |
| 128        | 0.30              | 35.3       | 36.2          |
| 256        | 0.02              | 32.6       | 32.9          |

**Figure B.6** Miss per 1000 instructions for instruction, data, and unified caches of different sizes. The percentage of instruction references is about 74%. The data are for two-way associative caches with 64-byte blocks for the same computer and benchmarks as [Figure B.4](#).

this problem is to divide it: one cache is dedicated to instructions and another to data. Separate caches are found in most recent processors, including the Opteron. Hence, it has a 64 KiB instruction cache as well as the 64 KiB data cache.

The processor knows whether it is issuing an instruction address or a data address, so there can be separate ports for both, thereby doubling the bandwidth between the memory hierarchy and the processor. Separate caches also offer the opportunity of optimizing each cache separately: different capacities, block sizes, and associativities may lead to better performance. (In contrast to the instruction caches and data caches of the Opteron, the terms *unified* or *mixed* are applied to caches that can contain either instructions or data.)

[Figure B.6](#) shows that instruction caches have lower miss rates than data caches. Separating instructions and data removes misses due to conflicts between instruction blocks and data blocks, but the split also fixes the cache space devoted to each type. Which is more important to miss rates? A fair comparison of separate instruction and data caches to unified caches requires the total cache size to be the same. For example, a separate 16 KiB instruction cache and 16 KiB data cache should be compared with a 32 KiB unified cache. Calculating the average miss rate with separate instruction and data caches necessitates knowing the percentage of memory references to each cache. From the data in [Appendix A](#) we find the split is  $100\% / (100\% + 26\% + 10\%)$  or about 74% instruction references to  $(26\% + 10\%) / (100\% + 26\% + 10\%)$  or about 26% data references. Splitting affects performance beyond what is indicated by the change in miss rates, as we will see shortly.

B.2

Cache Performance

Because instruction count is independent of the hardware, it is tempting to evaluate processor performance using that number. Such indirect performance measures have waylaid many a computer designer. The corresponding temptation for evaluating memory hierarchy performance is to concentrate on miss rate because it,

too, is independent of the speed of the hardware. As we will see, miss rate can be just as misleading as instruction count. A better measure of memory hierarchy performance is the *average memory access time*:

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

where *hit time* is the time to hit in the cache; we have seen the other two terms before. The components of average access time can be measured either in absolute time—say, 0.25–1.0 ns on a hit—or in the number of clock cycles that the processor waits for the memory—such as a miss penalty of 150–200 clock cycles. Remember that average memory access time is still an indirect measure of performance; although it is a better measure than miss rate, it is not a substitute for execution time.

This formula can help us decide between split caches and a unified cache.

---

**Example** Which has the lower miss rate: a 16 KiB instruction cache with a 16 KiB data cache or a 32 KiB unified cache? Use the miss rates in [Figure B.6](#) to help calculate the correct answer, assuming 36% of the instructions are data transfer instructions. Assume a hit takes 1 clock cycle and the miss penalty is 100 clock cycles. A load or store hit takes 1 extra clock cycle on a unified cache if there is only one cache port to satisfy two simultaneous requests. Using the pipelining terminology of [Chapter 3](#), the unified cache leads to a structural hazard. What is the average memory access time in each case? Assume write-through caches with a write buffer and ignore stalls due to the write buffer.

**Answer** First let's convert misses per 1000 instructions into miss rates. Solving the preceding general formula, the miss rate is

$$\text{Miss rate} = \frac{\frac{\text{Misses}}{1000 \text{ Instructions}}}{\frac{\text{Memory accesses}}{\text{Instruction}}}$$

Because every instruction access has exactly one memory access to fetch the instruction, the instruction miss rate is

$$\text{Miss rate}_{16\text{KB instruction}} = \frac{3.82/1000}{1.00} = 0.004$$

Because 36% of the instructions are data transfers, the data miss rate is

$$\text{Miss rate}_{16\text{KB data}} = \frac{40.9/1000}{0.36} = 0.114$$

The unified miss rate needs to account for instruction and data accesses:

$$\text{Miss rate}_{32\text{KB unified}} = \frac{43.3/1000}{1.00 + 0.36} = 0.0318$$

As stated herein, about 74% of the memory accesses are instruction references. Thus, the overall miss rate for the split caches is

$$(74\% \times 0.004) + (26\% \times 0.114) = 0.0326$$

Thus, a 32 KiB unified cache has a slightly lower effective miss rate than two 16 KiB caches.

The average memory access time formula can be divided into instruction and data accesses:

$$\begin{aligned} &\text{Average memory access time} \\ &= \% \text{ instructions} \times (\text{Hit time} + \text{Instruction miss rate} \times \text{Miss penalty}) \\ &\quad + \% \text{ data} \times (\text{Hit time} + \text{Data miss rate} \times \text{Miss penalty}) \end{aligned}$$

Therefore, the time for each organization is

$$\begin{aligned} &\text{Average memory access time}_{\text{split}} \\ &= 74\% \times (1 + 0.004 \times 200) + 26\% \times (1 + 0.114 \times 200) \\ &= (74\% \times 1.80) + (26\% \times 23.80) = 1.332 + 6.188 = 7.52 \end{aligned}$$

$$\begin{aligned} &\text{Average memory access time}_{\text{unified}} \\ &= 74\% \times (1 + 0.0318 \times 200) + 26\% \times (1 + 1 + 0.0318 \times 200) \\ &= (74\% \times 7.36) + (26\% \times 8.36) = 5.446 + 2.174 = 7.62 \end{aligned}$$

Hence, the split caches in this example—which offer two memory ports per clock cycle, thereby avoiding the structural hazard—have a better average memory access time than the single-ported unified cache despite having a worse effective miss rate.

---

## Average Memory Access Time and Processor Performance

An obvious question is whether average memory access time due to cache misses predicts processor performance.

First, there are other reasons for stalls, such as contention due to I/O devices using memory. Designers often assume that all memory stalls are due to cache misses, because the memory hierarchy typically dominates other reasons for stalls. We use this simplifying assumption here, but be sure to account for *all* memory stalls when calculating final performance.

Second, the answer also depends on the processor. If we have an in-order execution processor (see [Chapter 3](#)), then the answer is basically yes. The processor stalls during misses, and the memory stall time is strongly correlated to average memory access time. Let's make that assumption for now, but we'll return to out-of-order processors in the next subsection.

As stated in the previous section, we can model CPU time as:

$$\text{CPU time} = (\text{CPU execution clock cycles} + \text{Memory stall clock cycles}) \times \text{Clock cycle time}$$

This formula raises the question of whether the clock cycles for a cache hit should be considered part of CPU execution clock cycles or part of memory stall clock cycles. Although either convention is defensible, the most widely accepted is to include hit clock cycles in CPU execution clock cycles.

We can now explore the impact of caches on performance.

**Example** Let's use an in-order execution computer for the first example. Assume that the cache miss penalty is 200 clock cycles, and all instructions usually take 1.0 clock cycles (ignoring memory stalls). Assume that the average miss rate is 2%, there is an average of 1.5 memory references per instruction, and the average number of cache misses per 1000 instructions is 30. What is the impact on performance when behavior of the cache is included? Calculate the impact using both misses per instruction and miss rate.

**Answer**

$$\text{CPU time} = \text{IC} \times \left( \text{CPI}_{\text{execution}} + \frac{\text{Memory stall clock cycles}}{\text{Instruction}} \right) \times \text{Clock cycle time}$$

The performance, including cache misses, is

$$\begin{aligned} \text{CPU time}_{\text{with cache}} &= \text{IC} \times [1.0 + (30/1000 \times 200)] \times \text{Clock cycle time} \\ &= \text{IC} \times 7.00 \times \text{Clock cycle time} \end{aligned}$$

Now calculating performance using miss rate:

$$\begin{aligned} \text{CPU time} &= \text{IC} \times \left( \text{CPI}_{\text{execution}} + \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss penalty} \right) \times \text{Clock cycle time} \\ \text{CPU time}_{\text{with cache}} &= \text{IC} \times [1.0 + (1.5 \times 2\% \times 200)] \times \text{Clock cycle time} \\ &= \text{IC} \times 7.00 \times \text{Clock cycle time} \end{aligned}$$

The clock cycle time and instruction count are the same, with or without a cache. Thus, CPU time increases sevenfold, with CPI from 1.00 for a “perfect cache” to 7.00 with a cache that can miss. Without any memory hierarchy at all the CPI would increase again to  $1.0 + 200 \times 1.5$  or 301—a factor of more than 40 times longer than a system with a cache!

As this example illustrates, cache behavior can have enormous impact on performance. Furthermore, cache misses have a double-barreled impact on a processor with a low CPI and a fast clock:

1. The lower the  $\text{CPI}_{\text{execution}}$ , the higher the *relative* impact of a fixed number of cache miss clock cycles.
2. When calculating CPI, the cache miss penalty is measured in processor clock cycles for a miss. Therefore, even if memory hierarchies for two computers are

identical, the processor with the higher clock rate has a larger number of clock cycles per miss and hence a higher memory portion of CPI.

The importance of the cache for processors with low CPI and high clock rates is thus greater, and, consequently, greater is the danger of neglecting cache behavior in assessing performance of such computers. Amdahl's Law strikes again!

Although minimizing average memory access time is a reasonable goal—and we will use it in much of this appendix—keep in mind that the final goal is to reduce processor execution time. The next example shows how these two can differ.

---

**Example** What is the impact of two different cache organizations on the performance of a processor? Assume that the CPI with a perfect cache is 1.0, the clock cycle time is 0.35 ns, there are 1.4 memory references per instruction, the size of both caches is 128 KiB, and both have a block size of 64 bytes. One cache is direct mapped and the other is two-way set associative. Figure B.5 shows that for set associative caches we must add a multiplexor to select between the blocks in the set depending on the tag match. Because the speed of the processor can be tied directly to the speed of a cache hit, assume the processor clock cycle time must be stretched 1.35 times to accommodate the selection multiplexor of the set associative cache. To the first approximation, the cache miss penalty is 65 ns for either cache organization. (In practice, it is normally rounded up or down to an integer number of clock cycles.) First, calculate the average memory access time and then processor performance. Assume the hit time is 1 clock cycle, the miss rate of a direct-mapped 128 KiB cache is 2.1%, and the miss rate for a two-way set associative cache of the same size is 1.9%.

**Answer** Average memory access time is

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

Thus, the time for each organization is

$$\text{Average memory access time}_{1\text{-way}} = 0.35 + (.021 \times 65) = 1.72 \text{ ns}$$

$$\text{Average memory access time}_{2\text{-way}} = 0.35 \times 1.35 + (.019 \times 65) = 1.71 \text{ ns}$$

The average memory access time is better for the two-way set-associative cache. The processor performance is

$$\begin{aligned} \text{CPU time} &= \text{IC} \times \left( \text{CPI}_{\text{execution}} + \frac{\text{Misses}}{\text{Instruction}} \times \text{Miss penalty} \right) \times \text{Clock cycle time} \\ &= \text{IC} \times \left[ (\text{CPI}_{\text{execution}} \times \text{Clock cycle time}) \right. \\ &\quad \left. + \left( \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss penalty} \times \text{Clock cycle time} \right) \right] \end{aligned}$$

Substituting 65 ns for (Miss penalty  $\times$  Clock cycle time), the performance of each cache organization is

$$\text{CPU time}_{1\text{-way}} = \text{IC} \times [1.0 \times 0.35 + (0.021 \times 1.4 \times 65)] = 2.26 \times \text{IC}$$

$$\text{CPU time}_{2\text{-way}} = \text{IC} \times [1.0 \times 0.35 \times 1.35 + (0.019 \times 1.4 \times 65)] = 2.20 \times \text{IC}$$

and relative performance is

$$\frac{\text{CPU time}_{2\text{-way}}}{\text{CPU time}_{1\text{-way}}} = \frac{2.26 \times \text{Instruction count}}{2.20 \times \text{Instruction count}} = 1.03$$

In contrast to the results of average memory access time comparison, the direct-mapped cache leads to slightly better average performance because the clock cycle is stretched for *all* instructions for the two-way set associative case, even if there are fewer misses. Because CPU time is our bottom-line evaluation and because direct mapped is simpler to build, the preferred cache is direct mapped in this example.

---

## Miss Penalty and Out-of-Order Execution Processors

For an out-of-order execution processor, how do you define “miss penalty”? Is it the full latency of the miss to memory, or is it just the “exposed” or nonoverlapped latency when the processor must stall? This question does not arise in processors that stall until the data miss completes.

Let’s redefine memory stalls to lead to a new definition of miss penalty as non-overlapped latency:

$$\frac{\text{Memory stall cycles}}{\text{Instruction}} = \frac{\text{Misses}}{\text{Instruction}} \times (\text{Total miss latency} - \text{Overlapped miss latency})$$

Similarly, as some out-of-order processors stretch the hit time, that portion of the performance equation could be divided by total hit latency less overlapped hit latency. This equation could be further expanded to account for contention for memory resources in an out-of-order processor by dividing total miss latency into latency without contention and latency due to contention. Let’s just concentrate on miss latency.

We now have to decide the following:

- *Length of memory latency*—What to consider as the start and the end of a memory operation in an out-of-order processor.
- *Length of latency overlap*—What is the start of overlap with the processor (or, equivalently, when do we say a memory operation is stalling the processor)?

Given the complexity of out-of-order execution processors, there is no single correct definition.

Because only committed operations are seen at the retirement pipeline stage, we say a processor is stalled in a clock cycle if it does not retire the maximum possible number of instructions in that cycle. We attribute that stall to the first instruction that could not be retired. This definition is by no means foolproof. For example, applying an optimization to improve a certain stall time may not always improve execution time because another type of stall—hidden behind the targeted stall—may now be exposed.

For latency, we could start measuring from the time the memory instruction is queued in the instruction window, or when the address is generated, or when the instruction is actually sent to the memory system. Any option works as long as it is used in a consistent fashion.

---

**Example** Let's redo the preceding example, but this time we assume the processor with the longer clock cycle time supports out-of-order execution yet still has a direct-mapped cache. Assume 30% of the 65 ns miss penalty can be overlapped; that is, the average CPU memory stall time is now 45.5 ns.

**Answer** Average memory access time for the out-of-order (OOO) computer is

$$\text{Average memory access time}_{1\text{-way},\text{OOO}} = 0.35 \times 1.35 + (0.021 \times 45.5) = 1.43 \text{ ns}$$

The performance of the OOO cache is

$$\text{CUP time}_{1\text{-way},\text{OOO}} = \text{IC} \times [1.6 \times 0.35 \times 1.35 + (0.021 \times 1.4 \times 45.5)] = 2.09 \times \text{IC}$$

Hence, despite a much slower clock cycle time and the higher miss rate of a direct-mapped cache, the out-of-order computer can be slightly faster if it can hide 30% of the miss penalty.

---

In summary, although the state of the art in defining and measuring memory stalls for out-of-order processors is complex, be aware of the issues because they significantly affect performance. The complexity arises because out-of-order processors tolerate some latency due to cache misses without hurting performance. Consequently, designers usually use simulators of the out-of-order processor and memory when evaluating trade-offs in the memory hierarchy to be sure that an improvement that helps the average memory latency actually helps program performance.

To help summarize this section and to act as a handy reference, [Figure B.7](#) lists the cache equations in this appendix.

$$2^{\text{index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}}$$

$$\text{CPU execution time} = (\text{CPU clock cycles} + \text{Memory stall cycles}) \times \text{Clock cycle time}$$

$$\text{Memory stall cycles} = \text{Number of misses} \times \text{Miss penalty}$$

$$\text{Memory stall cycles} = \text{IC} \times \frac{\text{Misses}}{\text{Instruction}} \times \text{Miss penalty}$$

$$\frac{\text{Misses}}{\text{Instruction}} = \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}}$$

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

$$\text{CPU execution time} = \text{IC} \times \left( \text{CPI}_{\text{execution}} + \frac{\text{Memory stall clock cycles}}{\text{Instruction}} \right) \times \text{Clock cycle time}$$

$$\text{CPU execution time} = \text{IC} \times \left( \text{CPI}_{\text{execution}} + \frac{\text{Misses}}{\text{Instruction}} \times \text{Miss penalty} \right) \times \text{Clock cycle time}$$

$$\text{CPU execution time} = \text{IC} \times \left( \text{CPI}_{\text{execution}} + \text{Miss rate} \times \frac{\text{Memory accesses}}{\text{Instruction}} \times \text{Miss penalty} \right) \times \text{Clock cycle time}$$

$$\frac{\text{Memory stall cycles}}{\text{Instruction}} = \frac{\text{Misses}}{\text{Instruction}} \times (\text{Total miss latency} - \text{Overlapped miss latency})$$

$$\text{Average memory access time} = \text{Hit time}_{L1} + \text{Miss rate}_{L1} \times (\text{Hit time}_{L2} + \text{Miss rate}_{L2} \times \text{Miss penalty}_{L2})$$

$$\frac{\text{Memory stall cycles}}{\text{Instruction}} = \frac{\text{Misses}_{L1}}{\text{Instruction}} \times \text{Hit time}_{L2} + \frac{\text{Misses}_{L2}}{\text{Instruction}} \times \text{Miss penalty}_{L2}$$

**Figure B.7 Summary of performance equations in this appendix.** The first equation calculates the cache index size, and the rest help evaluate performance. The final two equations deal with multilevel caches, which are explained early in the next section. They are included here to help make the figure a useful reference.

### B.3

## Six Basic Cache Optimizations

The average memory access time formula gave us a framework to present cache optimizations for improving cache performance:

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

Hence, we organize six cache optimizations into three categories:

- *Reducing the miss rate*—larger block size, larger cache size, and higher associativity
- *Reducing the miss penalty*—multilevel caches and giving reads priority over writes
- *Reducing the time to hit in the cache*—avoiding address translation when indexing the cache

Figure B.18 on page B-40 concludes this section with a summary of the implementation complexity and the performance benefits of these six techniques.

The classical approach to improving cache behavior is to reduce miss rates, and we present three techniques to do so. To gain better insights into the causes of misses, we first start with a model that sorts all misses into three simple categories:

- *Compulsory*—The very first access to a block *cannot* be in the cache, so the block must be brought into the cache. These are also called *cold-start misses* or *first-reference misses*.
- *Capacity*—If the cache cannot contain all the blocks needed during execution of a program, capacity misses (in addition to compulsory misses) will occur because of blocks being discarded and later retrieved.
- *Conflict*—If the block placement strategy is set associative or direct mapped, conflict misses (in addition to compulsory and capacity misses) will occur because a block may be discarded and later retrieved if too many blocks map to its set. These misses are also called *collision misses*. The idea is that hits in a fully associative cache that become misses in an  $n$ -way set-associative cache are due to more than  $n$  requests on some popular sets.

(Chapter 5 adds a fourth C, for *coherency* misses due to cache flushes to keep multiple caches coherent in a multiprocessor; we won't consider those here.)

Figure B.8 shows the relative frequency of cache misses, broken down by the three C's. Compulsory misses are those that occur in an infinite cache. Capacity misses are those that occur in a fully associative cache. Conflict misses are those that occur going from fully associative to eight-way associative, four-way associative, and so on. Figure B.9 presents the same data graphically. The top graph shows absolute miss rates; the bottom graph plots the percentage of all the misses by type of miss as a function of cache size.

To show the benefit of associativity, conflict misses are divided into misses caused by each decrease in associativity. Here are the four divisions of conflict misses and how they are calculated:

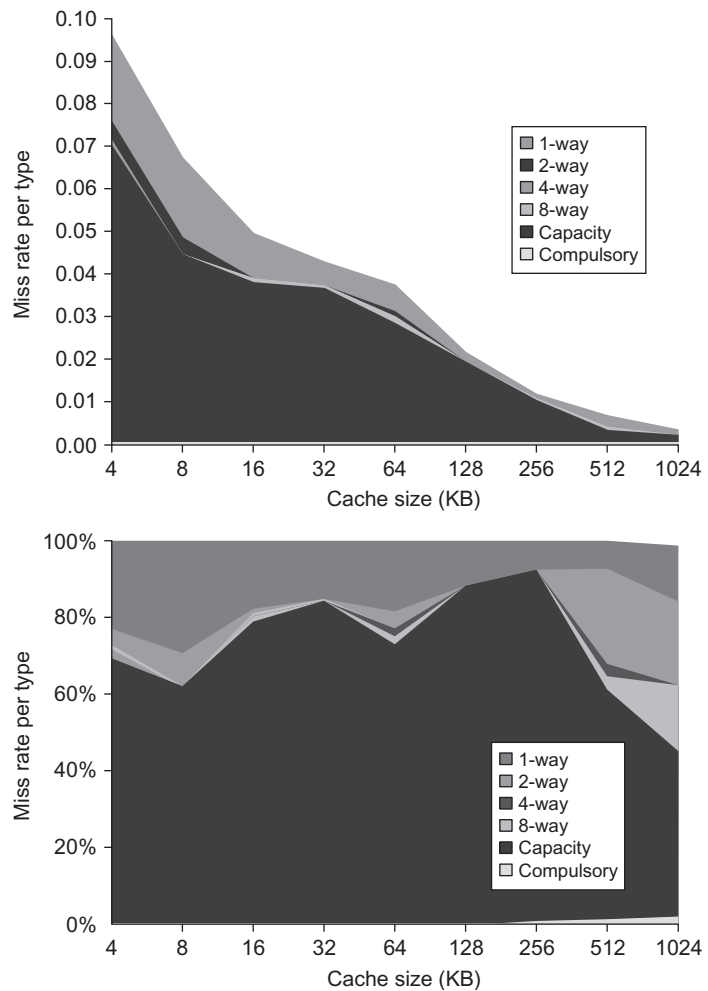

- *Eight-way*—Conflict misses due to going from fully associative (no conflicts) to eight-way associative
- *Four-way*—Conflict misses due to going from eight-way associative to four-way associative
- *Two-way*—Conflict misses due to going from four-way associative to two-way associative
- *One-way*—Conflict misses due to going from two-way associative to one-way associative (direct mapped)

As we can see from the figures, the compulsory miss rate of the SPEC2000 programs is very small, as it is for many long-running programs.

Having identified the three C's, what can a computer designer do about them? Conceptually, conflicts are the easiest: Fully associative placement avoids all

| Cache size (KiB) | Degree associative | Total miss rate | Miss rate components (relative percent)<br>(sum = 100% of total miss rate) |      |          |      |          |     |
|------------------|--------------------|-----------------|----------------------------------------------------------------------------|------|----------|------|----------|-----|
|                  |                    |                 | Compulsory                                                                 |      | Capacity |      | Conflict |     |
| 4                | 1-way              | 0.098           | 0.0001                                                                     | 0.1% | 0.070    | 72%  | 0.027    | 28% |
| 4                | 2-way              | 0.076           | 0.0001                                                                     | 0.1% | 0.070    | 93%  | 0.005    | 7%  |
| 4                | 4-way              | 0.071           | 0.0001                                                                     | 0.1% | 0.070    | 99%  | 0.001    | 1%  |
| 4                | 8-way              | 0.071           | 0.0001                                                                     | 0.1% | 0.070    | 100% | 0.000    | 0%  |
| 8                | 1-way              | 0.068           | 0.0001                                                                     | 0.1% | 0.044    | 65%  | 0.024    | 35% |
| 8                | 2-way              | 0.049           | 0.0001                                                                     | 0.1% | 0.044    | 90%  | 0.005    | 10% |
| 8                | 4-way              | 0.044           | 0.0001                                                                     | 0.1% | 0.044    | 99%  | 0.000    | 1%  |
| 8                | 8-way              | 0.044           | 0.0001                                                                     | 0.1% | 0.044    | 100% | 0.000    | 0%  |
| 16               | 1-way              | 0.049           | 0.0001                                                                     | 0.1% | 0.040    | 82%  | 0.009    | 17% |
| 16               | 2-way              | 0.041           | 0.0001                                                                     | 0.2% | 0.040    | 98%  | 0.001    | 2%  |
| 16               | 4-way              | 0.041           | 0.0001                                                                     | 0.2% | 0.040    | 99%  | 0.000    | 0%  |
| 16               | 8-way              | 0.041           | 0.0001                                                                     | 0.2% | 0.040    | 100% | 0.000    | 0%  |
| 32               | 1-way              | 0.042           | 0.0001                                                                     | 0.2% | 0.037    | 89%  | 0.005    | 11% |
| 32               | 2-way              | 0.038           | 0.0001                                                                     | 0.2% | 0.037    | 99%  | 0.000    | 0%  |
| 32               | 4-way              | 0.037           | 0.0001                                                                     | 0.2% | 0.037    | 100% | 0.000    | 0%  |
| 32               | 8-way              | 0.037           | 0.0001                                                                     | 0.2% | 0.037    | 100% | 0.000    | 0%  |
| 64               | 1-way              | 0.037           | 0.0001                                                                     | 0.2% | 0.028    | 77%  | 0.008    | 23% |

**Figure B.8 Total miss rate for each size cache and percentage of each according to the three C's.** Compulsory misses are independent of cache size, while capacity misses decrease as capacity increases, and conflict misses decrease as associativity increases. [Figure B.9](#) shows the same information graphically. Note that a direct-mapped cache of size  $N$  has about the same miss rate as a two-way set-associative cache of size  $N/2$  up through 128 K. Caches larger than 128 KiB do not prove that rule. Note that the Capacity column is also the fully associative miss rate. Data were collected as in [Figure B.4](#) using LRU replacement.

**Figure B.9** Total miss rate (top) and distribution of miss rate (bottom) for each size cache according to the three C's for the data in [Figure B.8](#). The top diagram shows the actual data cache miss rates, while the bottom diagram shows the percentage in each category. (*Space allows the graphs to show one extra cache size than can fit in [Figure B.8](#).*)

conflict misses. Full associativity is expensive in hardware, however, and may slow the processor clock rate (see the example on page B-29), leading to lower overall performance.

There is little to be done about capacity except to enlarge the cache. If the upper-level memory is much smaller than what is needed for a program, and a significant percentage of the time is spent moving data between two levels in the

hierarchy, the memory hierarchy is said to *thrash*. Because so many replacements are required, thrashing means the computer runs close to the speed of the lower-level memory, or maybe even slower because of the miss overhead.

Another approach to improving the three C's is to make blocks larger to reduce the number of compulsory misses, but, as we will see shortly, large blocks can increase other kinds of misses.

The three C's give insight into the cause of misses, but this simple model has its limits; it gives you insight into average behavior but may not explain an individual miss. For example, changing cache size changes conflict misses as well as capacity misses, because a larger cache spreads out references to more blocks. Thus, a miss might move from a capacity miss to a conflict miss as cache size changes. Similarly, changing the block size can sometimes reduce capacity misses (in addition to the expected reduction in compulsory misses), as [Gupta et al. \(2013\)](#) show.

Note also that the three C's also ignore replacement policy, because it is difficult to model and because, in general, it is less significant. In specific circumstances the replacement policy can actually lead to anomalous behavior, such as poorer miss rates for larger associativity, which contradicts the three C's model. (Some have proposed using an address trace to determine optimal placement in memory to avoid placement misses from the three C's model; we've not followed that advice here.)

Alas, many of the techniques that reduce miss rates also increase hit time or miss penalty. The desirability of reducing miss rates using the three optimizations must be balanced against the goal of making the whole system fast. This first example shows the importance of a balanced perspective.

## First Optimization: Larger Block Size to Reduce Miss Rate

The simplest way to reduce miss rate is to increase the block size. [Figure B.10](#) shows the trade-off of block size versus miss rate for a set of programs and cache sizes. Larger block sizes will reduce also compulsory misses. This reduction occurs because the principle of locality has two components: temporal locality and spatial locality. Larger blocks take advantage of spatial locality.

At the same time, larger blocks increase the miss penalty. Because they reduce the number of blocks in the cache, larger blocks may increase conflict misses and even capacity misses if the cache is small. Clearly, there is little reason to increase the block size to such a size that it *increases* the miss rate. There is also no benefit to reducing miss rate if it increases the average memory access time. The increase in miss penalty may outweigh the decrease in miss rate.

---

**Example** [Figure B.11](#) shows the actual miss rates plotted in [Figure B.10](#). Assume the memory system takes 80 clock cycles of overhead and then delivers 16 bytes every 2 clock cycles. Thus, it can supply 16 bytes in 82 clock cycles, 32 bytes in 84 clock cycles, and so on. Which block size has the smallest average memory access time for each cache size in [Figure B.11](#)?

**Figure B.10** Miss rate versus block size for five different-sized caches. Note that miss rate actually goes up if the block size is too large relative to the cache size. Each line represents a cache of different size. Figure B.11 shows the data used to plot these lines. Unfortunately, SPEC2000 traces would take too long if block size were included, so these data are based on SPEC92 on a DECstation 5000 (Gee et al. 1993).

**Answer** Average memory access time is

$$\text{Average memory access time} = \text{Hit time} + \text{Miss rate} \times \text{Miss penalty}$$

If we assume the hit time is 1 clock cycle independent of block size, then the access time for a 16-byte block in a 4 KiB cache is

$$\text{Average memory access time} = 1 + (8.57\% \times 82) = 8.027 \text{ clock cycles}$$

and for a 256-byte block in a 256 KiB cache the average memory access time is

$$\text{Average memory access time} = 1 + (0.49\% \times 112) = 1.549 \text{ clock cycles}$$

| Block size | Cache size |       |       |       |
|------------|------------|-------|-------|-------|
|            | 4K         | 16K   | 64K   | 256K  |
| 16         | 8.57%      | 3.94% | 2.04% | 1.09% |
| 32         | 7.24%      | 2.87% | 1.35% | 0.70% |
| 64         | 7.00%      | 2.64% | 1.06% | 0.51% |
| 128        | 7.78%      | 2.77% | 1.02% | 0.49% |
| 256        | 9.51%      | 3.29% | 1.15% | 0.49% |

**Figure B.11** Actual miss rate versus block size for the five different-sized caches in Figure B.10. Note that for a 4 KiB cache, 256-byte blocks have a higher miss rate than 32-byte blocks. In this example, the cache would have to be 256 KiB in order for a 256-byte block to decrease misses.

| Block size | Miss penalty | Cache size   |              |              |              |
|------------|--------------|--------------|--------------|--------------|--------------|
|            |              | 4K           | 16K          | 64K          | 256K         |
| 16         | 82           | 8.027        | 4.231        | 2.673        | 1.894        |
| 32         | 84           | <b>7.082</b> | 3.411        | 2.134        | 1.588        |
| 64         | 88           | 7.160        | <b>3.323</b> | <b>1.933</b> | <b>1.449</b> |
| 128        | 96           | 8.469        | 3.659        | 1.979        | 1.470        |
| 256        | 112          | 11.651       | 4.685        | 2.288        | 1.549        |

**Figure B.12** Average memory access time versus block size for five different-sized caches in [Figure B.10](#). Block sizes of 32 and 64 bytes dominate. The smallest average time per cache size is boldfaced.

[Figure B.12](#) shows the average memory access time for all block and cache sizes between those two extremes. The boldfaced entries show the fastest block size for a given cache size: 32 bytes for 4 KiB and 64 bytes for the larger caches. These sizes are, in fact, popular block sizes for processor caches today.

As in all of these techniques, the cache designer is trying to minimize both the miss rate and the miss penalty. The selection of block size depends on both the latency and bandwidth of the lower-level memory. High latency and high bandwidth encourage large block size because the cache gets many more bytes per miss for a small increase in miss penalty. Conversely, low latency and low bandwidth encourage smaller block sizes because there is little time saved from a larger block. For example, twice the miss penalty of a small block may be close to the penalty of a block twice the size. The larger number of small blocks may also reduce conflict misses. Note that [Figures B.10](#) and [B.12](#) show the difference between selecting a block size based on minimizing miss rate versus minimizing average memory access time.

After seeing the positive and negative impact of larger block size on compulsory and capacity misses, the next two subsections look at the potential of higher capacity and higher associativity.

## Second Optimization: Larger Caches to Reduce Miss Rate

The obvious way to reduce capacity misses in [Figures B.8](#) and [B.9](#) is to increase capacity of the cache. The obvious drawback is potentially longer hit time and higher cost and power. This technique has been especially popular in off-chip caches.

## Third Optimization: Higher Associativity to Reduce Miss Rate

[Figures B.8](#) and [B.9](#) show how miss rates improve with higher associativity. There are two general rules of thumb that can be gleaned from these figures. The first is

that eight-way set associative is for practical purposes as effective in reducing misses for these sized caches as fully associative. You can see the difference by comparing the eight-way entries to the capacity miss column in [Figure B.8](#), because capacity misses are calculated using fully associative caches.

The second observation, called the *2:1 cache rule of thumb*, is that a direct-mapped cache of size  $N$  has about the same miss rate as a two-way set associative cache of size  $N/2$ . This held in three C's figures for cache sizes less than 128 KiB.

Like many of these examples, improving one aspect of the average memory access time comes at the expense of another. Increasing block size reduces miss rate while increasing miss penalty, and greater associativity can come at the cost of increased hit time. Hence, the pressure of a fast processor clock cycle encourages simple cache designs, but the increasing miss penalty rewards associativity, as the following example suggests.

---

**Example** Assume that higher associativity would increase the clock cycle time as listed as follows:

$$\text{Clock cycle time}_{2\text{-way}} = 1.36 \times \text{Clock cycle time}_{1\text{-way}}$$

$$\text{Clock cycle time}_{4\text{-way}} = 1.44 \times \text{Clock cycle time}_{1\text{-way}}$$

$$\text{Clock cycle time}_{8\text{-way}} = 1.52 \times \text{Clock cycle time}_{1\text{-way}}$$

Assume that the hit time is 1 clock cycle, that the miss penalty for the direct-mapped case is 25 clock cycles to a level 2 cache (see next subsection) that never misses, and that the miss penalty need not be rounded to an integral number of clock cycles. Using [Figure B.8](#) for miss rates, for which cache sizes are each of these three statements true?

$$\text{Average memory access time}_{8\text{-way}} < \text{Average memory access time}_{4\text{-way}}$$

$$\text{Average memory access time}_{4\text{-way}} < \text{Average memory access time}_{2\text{-way}}$$

$$\text{Average memory access time}_{2\text{-way}} < \text{Average memory access time}_{1\text{-way}}$$

**Answer** Average memory access time for each associativity is

$$\begin{aligned} \text{Average memory access time}_{8\text{-way}} &= \text{Hit time}_{8\text{-way}} + \text{Miss rate}_{8\text{-way}} \times \text{Miss penalty}_{8\text{-way}} \\ &= 1.52 + \text{Miss rate}_{8\text{-way}} \times 25 \end{aligned}$$

$$\text{Average memory access time}_{4\text{-way}} = 1.44 + \text{Miss rate}_{4\text{-way}} \times 25$$

$$\text{Average memory access time}_{2\text{-way}} = 1.36 + \text{Miss rate}_{2\text{-way}} \times 25$$

$$\text{Average memory access time}_{1\text{-way}} = 1.00 + \text{Miss rate}_{1\text{-way}} \times 25$$

The miss penalty is the same time in each case, so we leave it as 25 clock cycles. For example, the average memory access time for a 4 KiB direct-mapped cache is

$$\text{Average memory access time}_{1\text{-way}} = 1.00 + (0.098 \times 25) = 3.44$$

and the time for a 512 KiB, eight-way set associative cache is

$$\text{Average memory access time}_{8\text{-way}} = 1.52 + (0.006 \times 25) = 1.66$$

Using these formulas and the miss rates from [Figure B.8](#), [Figure B.13](#) shows the average memory access time for each cache and associativity. The figure shows

| Cache size (KiB) | Associativity |             |             |             |
|------------------|---------------|-------------|-------------|-------------|
|                  | 1-way         | 2-way       | 4-way       | 8-way       |
| 4                | 3.44          | 3.25        | 3.22        | <b>3.28</b> |
| 8                | 2.69          | 2.58        | 2.55        | <b>2.62</b> |
| 16               | 2.23          | <b>2.40</b> | <b>2.46</b> | <b>2.53</b> |
| 32               | 2.06          | <b>2.30</b> | <b>2.37</b> | <b>2.45</b> |
| 64               | 1.92          | <b>2.14</b> | <b>2.18</b> | <b>2.25</b> |
| 128              | 1.52          | <b>1.84</b> | <b>1.92</b> | <b>2.00</b> |
| 256              | 1.32          | <b>1.66</b> | <b>1.74</b> | <b>1.82</b> |
| 512              | 1.20          | <b>1.55</b> | <b>1.59</b> | <b>1.66</b> |

**Figure B.13** Average memory access time using miss rates in [Figure B.8](#) for parameters in the example. *Boldface* type means that this time is higher than the number to the left, that is, higher associativity *increases* average memory access time.

that the formulas in this example hold for caches less than or equal to 8 KiB for up to four-way associativity. Starting with 16 KiB, the greater hit time of larger associativity outweighs the time saved due to the reduction in misses.

Note that we did not account for the slower clock rate on the rest of the program in this example, thereby understating the advantage of direct-mapped cache.

### Fourth Optimization: Multilevel Caches to Reduce Miss Penalty

Reducing cache misses had been the traditional focus of cache research, but the cache performance formula assures us that improvements in miss penalty can be just as beneficial as improvements in miss rate. Moreover, Figure 2.2 on page 80 shows that technology trends have improved the speed of processors faster than DRAMs, making the relative cost of miss penalties increase over time.

This performance gap between processors and memory leads the architect to this question: Should I make the cache faster to keep pace with the speed of processors, or make the cache larger to overcome the widening gap between the processor and main memory?

One answer is, do both. Adding another level of cache between the original cache and memory simplifies the decision. The first-level cache can be small enough to match the clock cycle time of the fast processor. Yet, the second-level cache can be large enough to capture many accesses that would go to main memory, thereby lessening the effective miss penalty.

Although the concept of adding another level in the hierarchy is straightforward, it complicates performance analysis. Definitions for a second level of cache are not always straightforward. Let’s start with the definition of *average memory access time* for a two-level cache. Using the subscripts L1 and L2 to refer, respectively, to a first-level and a second-level cache, the original formula is

$$\text{Average memory access time} = \text{Hit time}_{L1} + \text{Miss rate}_{L1} \times \text{Miss penalty}_{L1}$$

and

$$\text{Miss penalty}_{L1} = \text{Hit time}_{L2} + \text{Miss rate}_{L2} \times \text{Miss penalty}_{L2}$$

so

$$\begin{aligned} \text{Average memory access time} = & \text{Hit time}_{L1} + \text{Miss rate}_{L1} \\ & \times (\text{Hit time}_{L2} + \text{Miss rate}_{L2} \times \text{Miss penalty}_{L2}) \end{aligned}$$

In this formula, the second-level miss rate is measured on the leftovers from the first-level cache. To avoid ambiguity, these terms are adopted here for a two-level cache system:

- *Local miss rate*—This rate is simply the number of misses in a cache divided by the total number of memory accesses to this cache. As you would expect, for the first-level cache it is equal to  $\text{Miss rate}_{L1}$ , and for the second-level cache it is  $\text{Miss rate}_{L2}$ .
- *Global miss rate*—The number of misses in the cache divided by the total number of memory accesses generated by the processor. Using the terms above, the global miss rate for the first-level cache is still just  $\text{Miss rate}_{L1}$ , but for the second-level cache it is  $\text{Miss rate}_{L1} \times \text{Miss rate}_{L2}$ .

This local miss rate is large for second-level caches because the first-level cache skims the cream of the memory accesses. This is why the global miss rate is the more useful measure: It indicates what fraction of the memory accesses that leave the processor go all the way to memory.

Here is a place where the misses per instruction metric shines. Instead of confusion about local or global miss rates, we just expand memory stalls per instruction to add the impact of a second-level cache.

$$\begin{aligned} \text{Average memory stalls per instruction} = & \text{Misses per instruction}_{L1} \times \text{Hit time}_{L2} \\ & + \text{Misses per instruction}_{L2} \times \text{Miss penalty}_{L2} \end{aligned}$$

---

**Example** Suppose that in 1000 memory references there are 40 misses in the first-level cache and 20 misses in the second-level cache. What are the various miss rates? Assume the miss penalty from the L2 cache to memory is 200 clock cycles, the hit time of the L2 cache is 10 clock cycles, the hit time of L1 is 1 clock cycle, and there are 1.5 memory references per instruction. What is the average memory access time and average stall cycles per instruction? Ignore the impact of writes.

**Answer** The miss rate (either local or global) for the first-level cache is 40/1000 or 4%. The local miss rate for the second-level cache is 20/40 or 50%. The global miss rate of the second-level cache is 20/1000 or 2%. Then

$$\begin{aligned} \text{Average memory access time} = & \text{Hit time}_{L1} + \text{Miss rate}_{L1} \times (\text{Hit time}_{L2} + \text{Miss rate}_{L2} \times \text{Miss penalty}_{L2}) \\ = & 1 + 4\% \times (10 + 50\% \times 200) = 1 + 4\% \times 110 = 5.4 \text{ clock cycles} \end{aligned}$$

To see how many misses we get per instruction, we divide 1000 memory references by 1.5 memory references per instruction, which yields 667 instructions. Thus, we need to multiply the misses by 1.5 to get the number of misses per 1000 instructions. We have  $40 \times 1.5$  or 60 L1 misses, and  $20 \times 1.5$  or 30 L2 misses, per 1000 instructions. For average memory stalls per instruction, assuming the misses are distributed uniformly between instructions and data:

$$\begin{aligned} \text{Average memory stalls per instruction} &= \text{Misses per instruction}_{L1} \times \text{Hit time}_{L2} + \text{Misses per instruction}_{L2} \\ &\quad \times \text{Miss penalty}_{L2} \\ &= (60/1000) \times 10 + (30/1000) \times 200 \\ &= 0.060 \times 10 + 0.030 \times 200 = 6.6 \text{ clock cycles} \end{aligned}$$

If we subtract the L1 hit time from the average memory access time (AMAT) and then multiply by the average number of memory references per instruction, we get the same average memory stalls per instruction:

$$(5.4 - 1.0) \times 1.5 = 4.4 \times 1.5 = 6.6 \text{ clock cycles}$$

As this example shows, there may be less confusion with multilevel caches when calculating using misses per instruction versus miss rates.

---

Note that these formulas are for combined reads and writes, assuming a write-back first-level cache. Obviously, a write-through first-level cache will send *all* writes to the second level, not just the misses, and a write buffer might be used.

Figures B.14 and B.15 show how miss rates and relative execution time change with the size of a second-level cache for one design. From these figures we can gain two insights. The first is that the global cache miss rate is very similar to the single cache miss rate of the second-level cache, provided that the second-level cache is much larger than the first-level cache. Hence, our intuition and knowledge about the first-level caches apply. The second insight is that the local cache miss rate is *not* a good measure of secondary caches; it is a function of the miss rate of the first-level cache, and hence can vary by changing the first-level cache. Thus, the global cache miss rate should be used when evaluating second-level caches.

With these definitions in place, we can consider the parameters of second-level caches. The foremost difference between the two levels is that the speed of the first-level cache affects the clock rate of the processor, while the speed of the second-level cache only affects the miss penalty of the first-level cache. Thus, we can consider many alternatives in the second-level cache that would be ill chosen for the first-level cache. There are two major questions for the design of the second-level cache: Will it lower the average memory access time portion of the CPI, and how much does it cost?

The initial decision is the size of a second-level cache. Since everything in the first-level cache is likely to be in the second-level cache, the second-level cache should be much bigger than the first. If second-level caches are just a little bigger, the local miss rate will be high. This observation inspires the design of huge second-level caches—the size of main memory in older computers!

**Figure B.14** Miss rates versus cache size for multilevel caches. Second-level caches *smaller* than the sum of the two 64 KiB first-level caches make little sense, as reflected in the high miss rates. After 256 KiB the single cache is within 10% of the global miss rates. The miss rate of a single-level cache versus size is plotted against the local miss rate and global miss rate of a second-level cache using a 32 KiB first-level cache. The L2 caches (unified) were two-way set associative with replacement. Each had split L1 instruction and data caches that were 64 KiB two-way set associative with LRU replacement. The block size for both L1 and L2 caches was 64 bytes. Data were collected as in Figure B.4.

One question is whether set associativity makes more sense for second-level caches.

**Example** Given the following data, what is the impact of second-level cache associativity on its miss penalty?

- Hit time<sub>L2</sub> for direct mapped = 10 clock cycles.
- Two-way set associativity increases hit time by 0.1 clock cycle to 10.1 clock cycles.
- Local miss rate<sub>L2</sub> for direct mapped = 25%.
- Local miss rate<sub>L2</sub> for two-way set associative = 20%.
- Miss penalty<sub>L2</sub> = 200 clock cycles.

**Answer** For a direct-mapped second-level cache, the first-level cache miss penalty is

$$\text{Miss penalty}_{1\text{-way } L2} = 10 + 25\% \times 200 = 60.0 \text{ clock cycles}$$

**Figure B.15 Relative execution time by second-level cache size.** The two bars are for different clock cycles for an L2 cache hit. The reference execution time of 1.00 is for an 8192 KiB second-level cache with a 1-clock-cycle latency on a second-level hit. These data were collected the same way as in Figure B.14, using a simulator to imitate the Alpha 21264.

Adding the cost of associativity increases the hit cost only 0.1 clock cycle, making the new first-level cache miss penalty:

$$\text{Miss penalty}_{2\text{-way L2}} = 10.1 + 20\% \times 200 = 50.1 \text{ clock cycles}$$

In reality, second-level caches are almost always synchronized with the first-level cache and processor. Accordingly, the second-level hit time must be an integral number of clock cycles. If we are lucky, we shave the second-level hit time to 10 cycles; if not, we round up to 11 cycles. Either choice is an improvement over the direct-mapped second-level cache:

$$\text{Miss penalty}_{2\text{-way L2}} = 10 + 20\% \times 200 = 50.0 \text{ clock cycles}$$

$$\text{Miss penalty}_{2\text{-way L2}} = 11 + 20\% \times 200 = 51.0 \text{ clock cycles}$$

Now we can reduce the miss penalty by reducing the *miss rate* of the second-level caches.

Another consideration concerns whether data in the first-level cache are in the second-level cache. *Multilevel inclusion* is the natural policy for memory hierarchies: L1 data are always present in L2. Inclusion is desirable because consistency between I/O and caches (or among caches in a multiprocessor) can be determined just by checking the second-level cache.

One drawback to inclusion is that measurements can suggest smaller blocks for the smaller first-level cache and larger blocks for the larger second-level cache. For example, the Pentium 4 has 64-byte blocks in its L1 caches and 128-byte blocks in its L2 cache. Inclusion can still be maintained with more work on a second-level miss. The second-level cache must invalidate all first-level blocks that map onto the second-level block to be replaced, causing a slightly higher first-level miss rate. To avoid such problems, many cache designers keep the block size the same in all levels of caches.

However, what if the designer can only afford an L2 cache that is slightly bigger than the L1 cache? Should a significant portion of its space be used as a redundant copy of the L1 cache? In such cases a sensible opposite policy is *multilevel exclusion*: L1 data are *never* found in an L2 cache. Typically, with exclusion a cache miss in L1 results in a swap of blocks between L1 and L2 instead of a replacement of an L1 block with an L2 block. This policy prevents wasting space in the L2 cache. For example, the AMD Opteron chip obeys the exclusion property using two 64 KiB L1 caches and 1 MiB L2 cache.

As these issues illustrate, although a novice might design the first- and second-level caches independently, the designer of the first-level cache has a simpler job given a compatible second-level cache. It is less of a gamble to use a write through, for example, if there is a write-back cache at the next level to act as a backstop for repeated writes and it uses multilevel inclusion.

The essence of all cache designs is balancing fast hits and few misses. For second-level caches, there are far fewer hits than in the first-level cache, so the emphasis shifts to fewer misses. This insight leads to much larger caches and techniques to lower the miss rate, such as higher associativity and larger blocks.

### Fifth Optimization: Giving Priority to Read Misses over Writes to Reduce Miss Penalty

This optimization serves reads before writes have been completed. We start with looking at the complexities of a write buffer.

With a write-through cache the most important improvement is a write buffer of the proper size. Write buffers, however, do complicate memory accesses because they might hold the updated value of a location needed on a read miss.

---

**Example** Look at this code sequence:

```
sd x3, 512(x0); M[512] ← R3 (cache index 0)
ld x1, 1024(x0); x1 ← M[1024] (cache index 0)
ld x2, 512(x0); x2 ← M[512] (cache index 0)
```

Assume a direct-mapped, write-through cache that maps 512 and 1024 to the same block, and a four-word write buffer that is not checked on a read miss. Will the value in x2 always be equal to the value in x3?

**Answer** Using the terminology from [Chapter 2](#), this is a read-after-write data hazard in memory. Let's follow a cache access to see the danger. The data in x3 are placed into the write buffer after the store. The following load uses the same cache index and is therefore a miss. The second load instruction tries to put the value in location 512 into register x2; this also results in a miss. If the write buffer hasn't completed writing to location 512 in memory, the read of location 512 will put the old, wrong value into the cache block, and then into x2. Without proper precautions, x3x1 would not be equal to x2!

---

The simplest way out of this dilemma is for the read miss to wait until the write buffer is empty. The alternative is to check the contents of the write buffer on a read miss, and if there are no conflicts and the memory system is available, let the read miss continue. Virtually all desktop and server processors use the latter approach, giving reads priority over writes.

The cost of writes by the processor in a write-back cache can also be reduced. Suppose a read miss will replace a dirty memory block. Instead of writing the dirty block to memory, and then reading memory, we could copy the dirty block to a buffer, then read memory, and *then* write memory. This way the processor read, for which the processor is probably waiting, will finish sooner. Similar to the previous situation, if a read miss occurs, the processor can either stall until the buffer is empty or check the addresses of the words in the buffer for conflicts.

Now that we have five optimizations that reduce cache miss penalties or miss rates, it is time to look at reducing the final component of average memory access time. Hit time is critical because it can affect the clock rate of the processor; in many processors today the cache access time limits the clock cycle rate, even for processors that take multiple clock cycles to access the cache. Hence, a fast hit time is multiplied in importance beyond the average memory access time formula because it helps everything.

## Sixth Optimization: Avoiding Address Translation During Indexing of the Cache to Reduce Hit Time

Even a small and simple cache must cope with the translation of a virtual address from the processor to a physical address to access memory. As described in [Section B.4](#), processors treat main memory as just another level of the memory hierarchy, and thus the address of the virtual memory that exists on disk must be mapped onto the main memory.

The guideline of making the common case fast suggests that we use virtual addresses for the cache, because hits are much more common than misses. Such caches are termed *virtual caches*, with *physical cache* used to identify the traditional cache that uses physical addresses. As we will shortly see, it is important to distinguish two tasks: indexing the cache and comparing addresses. Thus, the issues are whether a virtual or physical address is used to index the cache and

whether a virtual or physical address is used in the tag comparison. Full virtual addressing for both indices and tags eliminates address translation time from a cache hit. Then why doesn't everyone build virtually addressed caches?

One reason is protection. Page-level protection is checked as part of the virtual to physical address translation, and it must be enforced no matter what. One solution is to copy the protection information from the TLB on a miss, add a field to hold it, and check it on every access to the virtually addressed cache.

Another reason is that every time a process is switched, the virtual addresses refer to different physical addresses, requiring the cache to be flushed. [Figure B.16](#) shows the impact on miss rates of this flushing. One solution is to increase the width of the cache address tag with a *process-identifier tag* (PID). If the operating system assigns these tags to processes, it only need flush the cache when a PID is

**Figure B.16** Miss rate versus virtually addressed cache size of a program measured three ways: without process switches (uniproccess), with process switches using a process-identifier tag (PID), and with process switches but without PIDs (purge). PIDs increase the uniproccess absolute miss rate by 0.3%–0.6% and save 0.6%–4.3% over purging. [Agarwal \(1987\)](#) collected these statistics for the Ultrix operating system running on a VAX, assuming direct-mapped caches with a block size of 16 bytes. Note that the miss rate goes up from 128 to 256 K. Such nonintuitive behavior can occur in caches because changing size changes the mapping of memory blocks onto cache blocks, which can change the conflict miss rate.

recycled; that is, the PID distinguishes whether or not the data in the cache are for this program. Figure B.16 shows the improvement in miss rates by using PIDs to avoid cache flushes.

A third reason why virtual caches are not more popular is that operating systems and user programs may use two different virtual addresses for the same physical address. These duplicate addresses, called *synonyms* or *aliases*, could result in two copies of the same data in a virtual cache; if one is modified, the other will have the wrong value. With a physical cache this wouldn't happen, because the accesses would first be translated to the same physical cache block.

Hardware solutions to the synonym problem, called *antialiasing*, guarantee every cache block a unique physical address. For example, the AMD Opteron uses a 64 KiB instruction cache with a 4 KiB page and two-way set associativity; hence, the hardware must handle aliases involved with the three virtual address bits in the set index. It avoids aliases by simply checking all eight possible locations on a miss—two blocks in each of four sets—to be sure that none matches the physical address of the data being fetched. If one is found, it is invalidated, so when the new data are loaded into the cache their physical address is guaranteed to be unique.

Software can make this problem much easier by forcing aliases to share some address bits. An older version of UNIX from Sun Microsystems, for example, required all aliases to be identical in the last 18 bits of their addresses; this restriction is called *page coloring*. Note that page coloring is simply set associative mapping applied to virtual memory: the 4 KiB ( $2^{12}$ ) pages are mapped using 64 ( $2^6$ ) sets to ensure that the physical and virtual addresses match in the last 18 bits. This restriction means a direct-mapped cache that is  $2^{18}$  (256 K) bytes or smaller can never have duplicate physical addresses for blocks. From the perspective of the cache, page coloring effectively increases the page offset, as software guarantees that the last few bits of the virtual and physical page address are identical.

The final area of concern with virtual addresses is I/O. I/O typically uses physical addresses and thus would require mapping to virtual addresses to interact with a virtual cache. (The impact of I/O on caches is further discussed in Appendix D.)

One alternative to get the best of both virtual and physical caches is to use part of the page offset—the part that is identical in both virtual and physical addresses—to index the cache. At the same time as the cache is being read using that index, the virtual part of the address is translated, and the tag match uses physical addresses.

This alternative allows the cache read to begin immediately, and yet the tag comparison is still with physical addresses. The limitation of this *virtually indexed, physically tagged* alternative is that a direct-mapped cache can be no bigger than the page size. For example, in the data cache in Figure B.5 on page B-13, the index is 9 bits and the cache block offset is 6 bits. To use this trick, the virtual page size would have to be at least  $2^{(9+6)}$  bytes or 32 KiB. If not, a portion of the index must be translated from virtual to physical address. Figure B.17 shows the organization of the caches, translation lookaside buffers (TLBs), and virtual memory when this technique is used.

**Figure B.17** The overall picture of a hypothetical memory hierarchy going from virtual address to L2 cache access. The page size is 16 KiB. The TLB is two-way set associative with 256 entries. The L1 cache is a direct-mapped 16 KiB, and the L2 cache is a four-way set associative with a total of 4 MiB. Both use 64-byte blocks. The virtual address is 64 bits and the physical address is 40 bits.

Associativity can keep the index in the physical part of the address and yet still support a large cache. Recall that the size of the index is controlled by this formula:

$$2^{\text{Index}} = \frac{\text{Cache size}}{\text{Block size} \times \text{Set associativity}}$$

For example, doubling associativity and doubling the cache size does not change the size of the index. The IBM 3033 cache, as an extreme example, is 16-way set associative, even though studies show there is little benefit to miss rates above

| Technique                                          | Hit time | Miss penalty | Miss rate | Hardware complexity | Comment                                                                    |
|----------------------------------------------------|----------|--------------|-----------|---------------------|----------------------------------------------------------------------------|
| Larger block size                                  |          | –            | +         | 0                   | Trivial; Pentium 4L2 uses 128 bytes                                        |
| Larger cache size                                  | –        |              | +         | 1                   | Widely used, especially for L2 caches                                      |
| Higher associativity                               | –        |              | +         | 1                   | Widely used                                                                |
| Multilevel caches                                  |          | +            |           | 2                   | Costly hardware; harder if L1 block size $\neq$ L2 block size; widely used |
| Read priority over writes                          |          | +            |           | 1                   | Widely used                                                                |
| Avoiding address translation during cache indexing | +        |              |           | 1                   | Widely used                                                                |

**Figure B.18** Summary of basic cache optimizations showing impact on cache performance and complexity for the techniques in this appendix. Generally a technique helps only one factor. + means that the technique improves the factor, – means it hurts that factor, and blank means it has no impact. The complexity measure is subjective, with 0 being the easiest and 3 being a challenge.

8-way set associativity. This high associativity allows a 64 KiB cache to be addressed with a physical index, despite the handicap of 4 KiB pages in the IBM architecture.

### Summary of Basic Cache Optimization

The techniques in this section to improve miss rate, miss penalty, and hit time generally impact the other components of the average memory access equation as well as the complexity of the memory hierarchy. [Figure B.18](#) summarizes these techniques and estimates the impact on complexity, with + meaning that the technique improves the factor, – meaning it hurts that factor, and blank meaning it has no impact. No optimization in this figure helps more than one category.

## B.4

### Virtual Memory

... a system has been devised to make the core drum combination appear to the programmer as a single level store, the requisite transfers taking place automatically.

Kilburn et al. (1962)

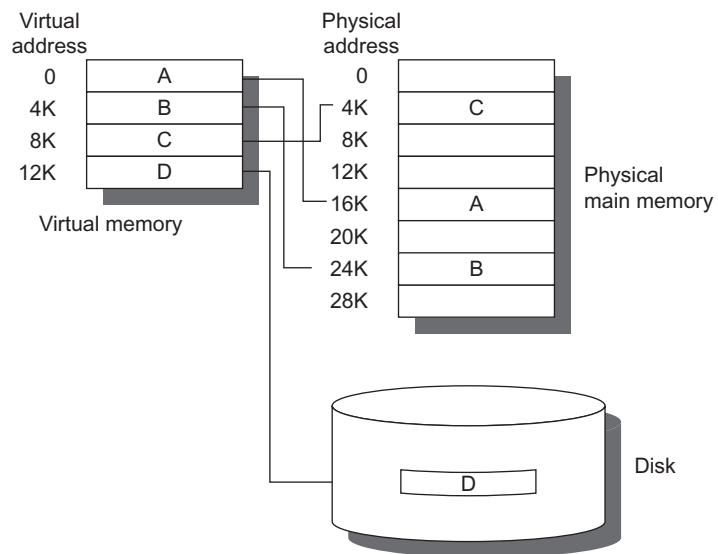

At any instant in time computers are running multiple processes, each with its own address space. (Processes are described in the next section.) It would be too expensive to dedicate a full address space worth of memory for each process, especially because many processes use only a small part of their address space. Hence, there must be a means of sharing a smaller amount of physical memory among many processes.

One way to do this, *virtual memory*, divides physical memory into blocks and allocates them to different processes. Inherent in such an approach must be a *protection* scheme that restricts a process to the blocks belonging only to that process. Most forms of virtual memory also reduce the time to start a program, because not all code and data need be in physical memory before a program can begin.

Although protection provided by virtual memory is essential for current computers, sharing is not the reason that virtual memory was invented. If a program became too large for physical memory, it was the programmer's job to make it fit. Programmers divided programs into pieces, then identified the pieces that were mutually exclusive, and loaded or unloaded these *overlays* under user program control during execution. The programmer ensured that the program never tried to access more physical main memory than was in the computer, and that the proper overlay was loaded at the proper time. As you can well imagine, this responsibility eroded programmer productivity.

Virtual memory was invented to relieve programmers of this burden; it automatically manages the two levels of the memory hierarchy represented by main memory and secondary storage. Figure B.19 shows the mapping of virtual memory to physical memory for a program with four pages.

In addition to sharing protected memory space and automatically managing the memory hierarchy, virtual memory also simplifies loading the program for execution. Called *relocation*, this mechanism allows the same program to run in any location in physical memory. The program in Figure B.19 can be placed anywhere

**Figure B.19** The logical program in its contiguous virtual address space is shown on the left. It consists of four pages, A, B, C, and D. The actual location of three of the blocks is in physical main memory and the other is located on the disk.

in physical memory or disk just by changing the mapping between them. (Prior to the popularity of virtual memory, processors would include a relocation register just for that purpose.) An alternative to a hardware solution would be software that changed all addresses in a program each time it was run.

Several general memory hierarchy ideas from [Chapter 1](#) about caches are analogous to virtual memory, although many of the terms are different. *Page* or *segment* is used for block, and *page fault* or *address fault* is used for miss. With virtual memory, the processor produces *virtual addresses* that are translated by a combination of hardware and software to *physical addresses*, which access main memory. This process is called *memory mapping* or *address translation*. Today, the two memory hierarchy levels controlled by virtual memory are DRAMs and magnetic disks. [Figure B.20](#) shows a typical range of memory hierarchy parameters for virtual memory.

There are further differences between caches and virtual memory beyond those quantitative ones mentioned in [Figure B.20](#):

- Replacement on cache misses is primarily controlled by hardware, while virtual memory replacement is primarily controlled by the operating system. The longer miss penalty means it's more important to make a good decision, so the operating system can be involved and take time deciding what to replace.
- The size of the processor address determines the size of virtual memory, but the cache size is independent of the processor address size.
- In addition to acting as the lower-level backing store for main memory in the hierarchy, secondary storage is also used for the file system. In fact, the file system occupies most of secondary storage. It is not usually in the address space.

| Parameter         | First-level cache                                     | Virtual memory                                          |
|-------------------|-------------------------------------------------------|---------------------------------------------------------|
| Block (page) size | 16–128 bytes                                          | 4096–65,536 bytes                                       |
| Hit time          | 1–3 clock cycles                                      | 100–200 clock cycles                                    |
| Miss penalty      | 8–200 clock cycles                                    | 1,000,000–10,000,000 clock cycles                       |
| (access time)     | (6–160 clock cycles)                                  | (800,000–8,000,000 clock cycles)                        |
| (transfer time)   | (2–40 clock cycles)                                   | (200,000–2,000,000 clock cycles)                        |
| Miss rate         | 0.1%–10%                                              | 0.00001%–0.001%                                         |
| Address mapping   | 25–45-bit physical address to 14–20-bit cache address | 32–64-bit virtual address to 25–45-bit physical address |

**Figure B.20** Typical ranges of parameters for caches and virtual memory. Virtual memory parameters represent increases of 10–1,000,000 times over cache parameters. Usually, first-level caches contain at most 1 MiB of data, whereas physical memory contains 256 MiB to 1 TB.

Virtual memory also encompasses several related techniques. Virtual memory systems can be categorized into two classes: those with fixed-size blocks, called *pages*, and those with variable-size blocks, called *segments*. Pages are typically fixed at 4096–8192 bytes, while segment size varies. The largest segment supported on any processor ranges from  $2^{16}$  bytes up to  $2^{32}$  bytes; the smallest segment is 1 byte. Figure B.21 shows how the two approaches might divide code and data.

The decision to use paged virtual memory versus segmented virtual memory affects the processor. Paged addressing has a single fixed-size address divided into page number and offset within a page, analogous to cache addressing. A single address does not work for segmented addresses; the variable size of segments requires 1 word for a segment number and 1 word for an offset within a segment, for a total of 2 words. An unsegmented address space is simpler for the compiler.

The pros and cons of these two approaches have been well documented in operating systems textbooks; Figure B.22 summarizes the arguments. Because of the

**Figure B.21** Example of how paging and segmentation divide a program.

|                         | Page                                                            | Segment                                                                        |
|-------------------------|-----------------------------------------------------------------|--------------------------------------------------------------------------------|
| Words per address       | One                                                             | Two (segment and offset)                                                       |
| Programmer visible?     | Invisible to application programmer                             | May be visible to application programmer                                       |
| Replacing a block       | Trivial (all blocks are the same size)                          | Difficult (must find contiguous, variable-size, unused portion of main memory) |
| Memory use inefficiency | Internal fragmentation (unused portion of page)                 | External fragmentation (unused pieces of main memory)                          |
| Efficient disk traffic  | Yes (adjust page size to balance access time and transfer time) | Not always (small segments may transfer just a few bytes)                      |

**Figure B.22** Paging versus segmentation. Both can waste memory, depending on the block size and how well the segments fit together in main memory. Programming languages with unrestricted pointers require both the segment and the address to be passed. A hybrid approach, called *paged segments*, shoots for the best of both worlds: segments are composed of pages, so replacing a block is easy, yet a segment may be treated as a logical unit.

replacement problem (the third line of the figure), few computers today use pure segmentation. Some computers use a hybrid approach, called *paged segments*, in which a segment is an integral number of pages. This simplifies replacement because memory need not be contiguous, and the full segments need not be in main memory. A more recent hybrid is for a computer to offer multiple page sizes, with the larger sizes being powers of 2 times the smallest page size. The IBM 405CR embedded processor, for example, allows 1 KiB, 4 KiB ( $2^2 \times 1$  KiB), 16 KiB ( $2^4 \times 1$  KiB), 64 KiB ( $2^6 \times 1$  KiB), 256 KiB ( $2^8 \times 1$  KiB), 1024 KiB ( $2^{10} \times 1$  KiB), and 4096 KiB ( $2^{12} \times 1$  KiB) to act as a single page.

## Four Memory Hierarchy Questions Revisited

We are now ready to answer the four memory hierarchy questions for virtual memory.

### *Q1: Where Can a Block be Placed in Main Memory?*

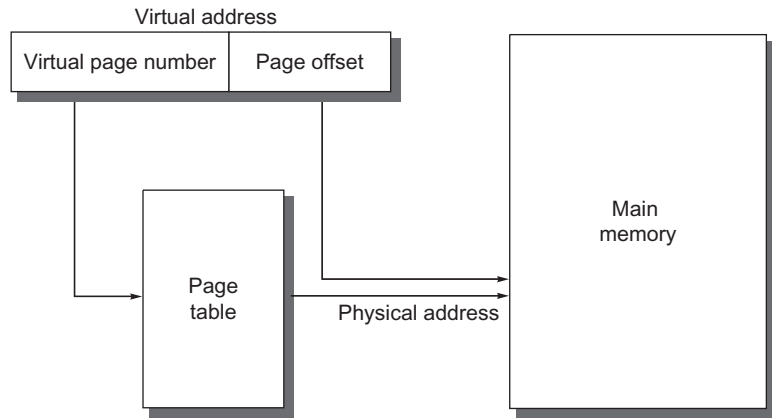

The miss penalty for virtual memory involves access to a rotating magnetic storage device and is therefore quite high. Given the choice of lower miss rates or a simpler placement algorithm, operating systems designers usually pick lower miss rates because of the exorbitant miss penalty. Thus, operating systems allow blocks to be placed anywhere in main memory. According to the terminology in [Figure B.2](#) on page B-8, this strategy would be labeled fully associative.

### *Q2: How Is a Block Found If It Is in Main Memory?*

Both paging and segmentation rely on a data structure that is indexed by the page or segment number. This data structure contains the physical address of the block. For segmentation, the offset is added to the segment's physical address to obtain the final physical address. For paging, the offset is simply concatenated to this physical page address (see [Figure B.23](#)).

This data structure, containing the physical page addresses, usually takes the form of a *page table*. Indexed by the virtual page number, the size of the table is the number of pages in the virtual address space. Given a 32-bit virtual address, 4 KiB pages, and 4 bytes per page table entry (PTE), the size of the page table would be  $(2^{32}/2^{12}) \times 2^2 = 2^{22}$  or 4 MiB.

To reduce the size of this data structure, some computers apply a hashing function to the virtual address. The hash allows the data structure to be the length of the number of *physical* pages in main memory. This number could be much smaller than the number of virtual pages. Such a structure is called an *inverted page table*. Using the previous example, a 512 MiB physical memory would only need 1 MiB ( $8 \times 512$  MiB/4 KiB) for an inverted page table; the extra 4 bytes per page table entry are for the virtual address. The HP/Intel IA-64 covers both bases by offering

**Figure B.23** The mapping of a virtual address to a physical address via a page table.

both traditional pages tables *and* inverted page tables, leaving the choice of mechanism to the operating system programmer.

To reduce address translation time, computers use a cache dedicated to these address translations, called a *translation lookaside buffer*, or simply *translation buffer*, described in more detail shortly.

### *Q3: Which Block Should be Replaced on a Virtual Memory Miss?*

As mentioned earlier, the overriding operating system guideline is minimizing page faults. Consistent with this guideline, almost all operating systems try to replace the least recently used (LRU) block because if the past predicts the future, that is the one less likely to be needed.

To help the operating system estimate LRU, many processors provide a *use bit* or *reference bit*, which is logically set whenever a page is accessed. (To reduce work, it is actually set only on a translation buffer miss, which is described shortly.) The operating system periodically clears the use bits and later records them so it can determine which pages were touched during a particular time period. By keeping track in this way, the operating system can select a page that is among the least recently referenced.

### *Q4: What Happens on a Write?*

The level below main memory contains rotating magnetic disks that take millions of clock cycles to access. Because of the great discrepancy in access time, no one has yet built a virtual memory operating system that writes through main memory to disk on every store by the processor. (This remark should not be interpreted as an opportunity to become famous by being the first to build one!) Thus, the write strategy is always write-back.

Because the cost of an unnecessary access to the next-lower level is so high, virtual memory systems usually include a dirty bit. It allows blocks to be written to disk only if they have been altered since being read from the disk.

## Techniques for Fast Address Translation

Page tables are usually so large that they are stored in main memory and are sometimes paged themselves. Paging means that every memory access logically takes at least twice as long, with one memory access to obtain the physical address and a second access to get the data. As mentioned in [Chapter 2](#), we use locality to avoid the extra memory access. By keeping address translations in a special cache, a memory access rarely requires a second access to translate the data. This special address translation cache is referred to as a *translation look aside buffer* (TLB), also called a *translation buffer* (TB).

A TLB entry is like a cache entry where the tag holds portions of the virtual address and the data portion holds a physical page frame number, protection field, valid bit, and usually a use bit and dirty bit. To change the physical page frame number or protection of an entry in the page table, the operating system must make sure the old entry is not in the TLB; otherwise, the system won't behave properly. Note that this dirty bit means the corresponding *page* is dirty, not that the address translation in the TLB is dirty nor that a particular block in the data cache is dirty. The operating system resets these bits by changing the value in the page table and then invalidates the corresponding TLB entry. When the entry is reloaded from the page table, the TLB gets an accurate copy of the bits.

[Figure B.24](#) shows the Opteron data TLB organization, with each step of the translation labeled. This TLB uses fully associative placement; thus, the translation begins (steps 1 and 2) by sending the virtual address to all tags. Of course, the tag must be marked valid to allow a match. At the same time, the type of memory access is checked for a violation (also in step 2) against protection information in the TLB.

For reasons similar to those in the cache case, there is no need to include the 12 bits of the page offset in the TLB. The matching tag sends the corresponding physical address through effectively a 40:1 multiplexor (step 3). The page offset is then combined with the physical page frame to form a full physical address (step 4). The address size is 40 bits.

Address translation can easily be on the critical path determining the clock cycle of the processor, so the Opteron uses virtually addressed, physically tagged L1 caches.

## Selecting a Page Size

The most obvious architectural parameter is the page size. Choosing the page is a question of balancing forces that favor a larger page size versus those favoring a smaller size. The following favor a larger size:

**Figure B.24** Operation of the Opteron data TLB during address translation. The four steps of a TLB hit are shown as *circled numbers*. This TLB has 40 entries. [Section B.5](#) describes the various protection and access fields of an Opteron page table entry.

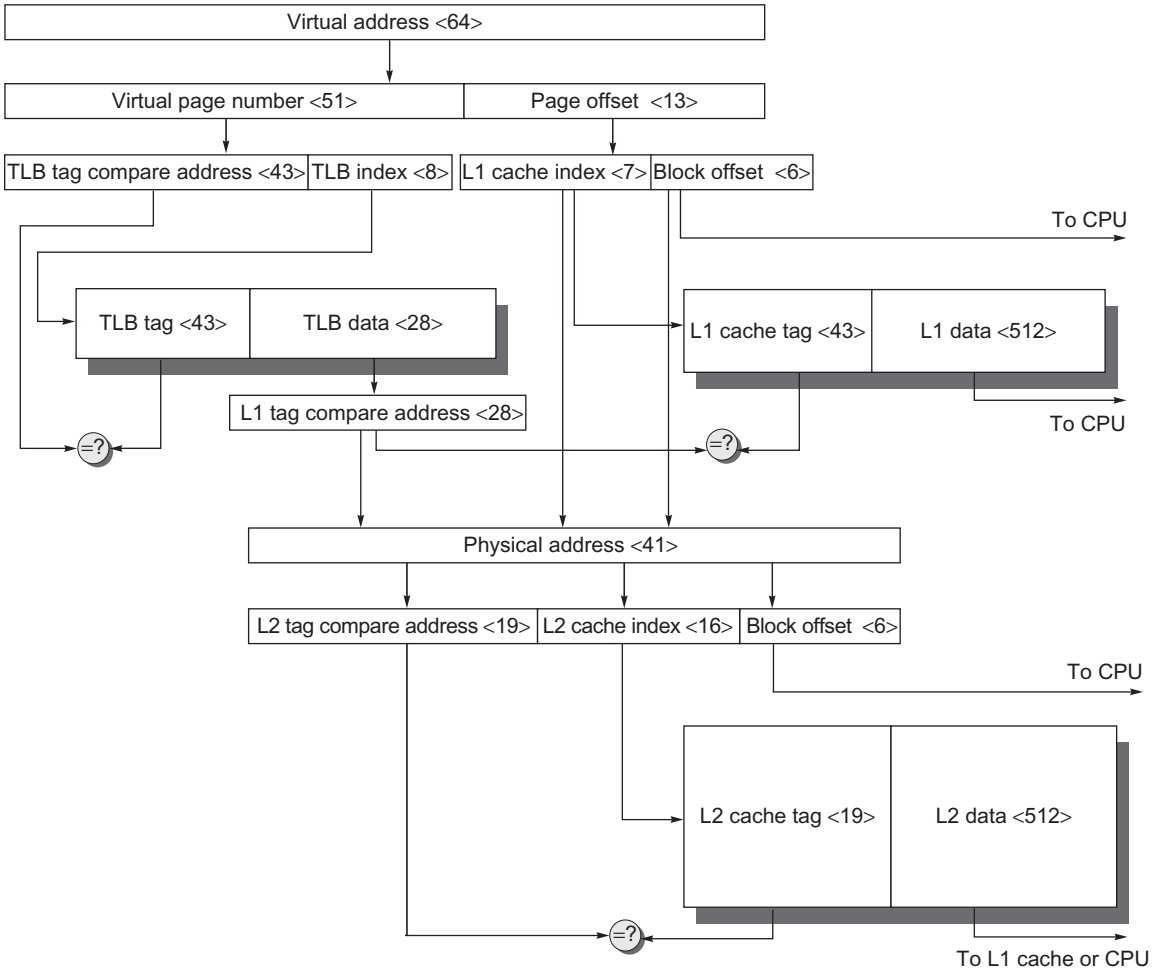

- The size of the page table is inversely proportional to the page size; memory (or other resources used for the memory map) can therefore be saved by making the pages bigger.
- As mentioned in [Section B.3](#), a larger page size can allow larger caches with fast cache hit times.
- Transferring larger pages to or from secondary storage, possibly over a network, is more efficient than transferring smaller pages.
- The number of TLB entries is restricted, so a larger page size means that more memory can be mapped efficiently, thereby reducing the number of TLB misses.

It is for this final reason that recent microprocessors have decided to support multiple page sizes; for some programs, TLB misses can be as significant on CPI as the cache misses.

The main motivation for a smaller page size is conserving storage. A small page size will result in less wasted storage when a contiguous region of virtual memory is not equal in size to a multiple of the page size. The term for this unused memory in a page is *internal fragmentation*. Assuming that each process has three primary segments (text, heap, and stack), the average wasted storage per process will be 1.5 times the page size. This amount is negligible for computers with hundreds of megabytes of memory and page sizes of 4–8 KiB. Of course, when the page sizes become very large (more than 32 KiB), storage (both main and secondary) could be wasted, as well as I/O bandwidth. A final concern is process start-up time; many processes are small, so a large page size would lengthen the time to invoke a process.

Summary of Virtual Memory and Caches

With virtual memory, TLBs, first-level caches, and second-level caches all mapping portions of the virtual and physical address space, it can get confusing what bits go where. Figure B.25 gives a hypothetical example going from a 64-bit virtual address to a 41-bit physical address with two levels of cache. This L1 cache is virtually indexed, and physically tagged because both the cache size and the page size are 8 KiB. The L2 cache is 4 MiB. The block size for both is 64 bytes.

**Figure B.25** The overall picture of a hypothetical memory hierarchy going from virtual address to L2 cache access. The page size is 8 KiB. The TLB is direct mapped with 256 entries. The L1 cache is a direct-mapped 8 KiB, and the L2 cache is a direct-mapped 4 MiB. Both use 64-byte blocks. The virtual address is 64 bits and the physical address is 41 bits. The primary difference between this simple figure and a real cache is replication of pieces of this figure.

First, the 64-bit virtual address is logically divided into a virtual page number and page offset. The former is sent to the TLB to be translated into a physical address, and the high bit of the latter is sent to the L1 cache to act as an index. If the TLB match is a hit, then the physical page number is sent to the L1 cache tag to check for a match. If it matches, it's an L1 cache hit. The block offset then selects the word for the processor.

If the L1 cache check results in a miss, the physical address is then used to try the L2 cache. The middle portion of the physical address is used as an index to the 4 MiB L2 cache. The resulting L2 cache tag is compared with the upper part of the physical address to check for a match. If it matches, we have an L2 cache hit, and the data are sent to the processor, which uses the block offset to select the desired word. On an L2 miss, the physical address is then used to get the block from memory.

Although this is a simple example, the major difference between this drawing and a real cache is replication. First, there is only one L1 cache. When there are two L1 caches, the top half of the diagram is duplicated. Note that this would lead to two TLBs, which is typical. Hence, one cache and TLB is for instructions, driven from the PC, and one cache and TLB is for data, driven from the effective address.

The second simplification is that all the caches and TLBs are direct mapped. If any were  $n$ -way set associative, then we would replicate each set of tag memory, comparators, and data memory  $n$  times and connect data memories with an  $n:1$  multiplexor to select a hit. Of course, if the total cache size remained the same, the cache index would also shrink by  $\log 2n$  bits according to the formula in [Figure B.7](#) on page B-22.

## B.5

## Protection and Examples of Virtual Memory

The invention of multiprogramming, where a computer would be shared by several programs running concurrently, led to new demands for protection and sharing among programs. These demands are closely tied to virtual memory in computers today, and so we cover the topic here along with two examples of virtual memory.

Multiprogramming leads to the concept of a *process*. Metaphorically, a process is a program's breathing air and living space—that is, a running program plus any state needed to continue running it. Time-sharing is a variation of multiprogramming that shares the processor and memory with several interactive users at the same time, giving the illusion that all users have their own computers. Thus, at any instant it must be possible to switch from one process to another. This exchange is called a *process switch* or *context switch*.

A process must operate correctly whether it executes continuously from start to finish, or it is interrupted repeatedly and switched with other processes. The responsibility for maintaining correct process behavior is shared by designers of the computer and the operating system. The computer designer must ensure that

the processor portion of the process state can be saved and restored. The operating system designer must guarantee that processes do not interfere with each others' computations.

The safest way to protect the state of one process from another would be to copy the current information to disk. However, a process switch would then take seconds—far too long for a time-sharing environment.

This problem is solved by operating systems partitioning main memory so that several different processes have their state in memory at the same time. This division means that the operating system designer needs help from the computer designer to provide protection so that one process cannot modify another. Besides protection, the computers also provide for sharing of code and data between processes, to allow communication between processes or to save memory by reducing the number of copies of identical information.

## Protecting Processes

Processes can be protected from one another by having their own page tables, each pointing to distinct pages of memory. Obviously, user programs must be prevented from modifying their page tables or protection would be circumvented.

Protection can be escalated, depending on the apprehension of the computer designer or the purchaser. *Rings* added to the processor protection structure expand memory access protection from two levels (user and kernel) to many more. Like a military classification system of top secret, secret, confidential, and unclassified, concentric rings of security levels allow the most trusted to access anything, the second most trusted to access everything except the innermost level, and so on. The “civilian” programs are the least trusted and, hence, have the most limited range of accesses. There may also be restrictions on what pieces of memory can contain code—execute protection—and even on the entrance point between the levels. The Intel 80x86 protection structure, which uses rings, is described later in this section. It is not clear whether rings are an improvement in practice over the simple system of user and kernel modes.

As the designer's apprehension escalates to trepidation, these simple rings may not suffice. Restricting the freedom given a program in the inner sanctum requires a new classification system. Instead of a military model, the analogy of this system is to keys and locks: a program can't unlock access to the data unless it has the key. For these keys, or *capabilities*, to be useful, the hardware and operating system must be able to explicitly pass them from one program to another without allowing a program itself to forge them. Such checking requires a great deal of hardware support if time for checking keys is to be kept low.

The 80x86 architecture has tried several of these alternatives over the years. Because backward compatibility is one of the guidelines of this architecture, the most recent versions of the architecture include all of its experiments in virtual memory. We'll go over two of the options here: first the older segmented address space and then the newer flat, 64-bit address space.

## A Segmented Virtual Memory Example: Protection in the Intel Pentium

The second system is the most dangerous system a man ever designs... The general tendency is to over-design the second system, using all the ideas and frills that were cautiously sidetracked on the first one.

**F. P. Brooks, Jr.**

*The Mythical Man-Month* (1975)

The original 8086 used segments for addressing, yet it provided nothing for virtual memory or for protection. Segments had base registers but no bound registers and no access checks, and before a segment register could be loaded the corresponding segment had to be in physical memory. Intel's dedication to virtual memory and protection is evident in the successors to the 8086, with a few fields extended to support larger addresses. This protection scheme is elaborate, with many details carefully designed to try to avoid security loopholes. We'll refer to it as IA-32. The next few pages highlight a few of the Intel safeguards; if you find the reading difficult, imagine the difficulty of implementing them!

The first enhancement is to double the traditional two-level protection model: the IA-32 has four levels of protection. The innermost level (0) corresponds to the traditional kernel mode, and the outermost level (3) is the least privileged mode. The IA-32 has separate stacks for each level to avoid security breaches between the levels. There are also data structures analogous to traditional page tables that contain the physical addresses for segments, as well as a list of checks to be made on translated addresses.

The Intel designers did not stop there. The IA-32 divides the address space, allowing both the operating system and the user access to the full space. The IA-32 user can call an operating system routine in this space and even pass parameters to it while retaining full protection. This safe call is not a trivial action, because the stack for the operating system is different from the user's stack. Moreover, the IA-32 allows the operating system to maintain the protection level of the *called* routine for the parameters that are passed to it. This potential loophole in protection is prevented by not allowing the user process to ask the operating system to access something indirectly that it would not have been able to access itself. (Such security loopholes are called *Trojan horses*.)

The Intel designers were guided by the principle of trusting the operating system as little as possible, while supporting sharing and protection. As an example of the use of such protected sharing, suppose a payroll program writes checks and also updates the year-to-date information on total salary and benefits payments. Thus, we want to give the program the ability to read the salary and year-to-date information and modify the year-to-date information but not the salary. We will see the mechanism to support such features shortly. In the rest of this subsection, we will look at the big picture of the IA-32 protection and examine its motivation.

### *Adding Bounds Checking and Memory Mapping*

The first step in enhancing the Intel processor was getting the segmented addressing to check bounds as well as supply a base. Rather than a base address, the segment registers in the IA-32 contain an index to a virtual memory data structure called a *descriptor table*. Descriptor tables play the role of traditional page tables. On the IA-32 the equivalent of a page table entry is a *segment descriptor*. It contains fields found in PTEs:

- *Present bit*—Equivalent to the PTE valid bit, used to indicate this is a valid translation
- *Base field*—Equivalent to a page frame address, containing the physical address of the first byte of the segment
- *Access bit*—Like the reference bit or use bit in some architectures that is helpful for replacement algorithms
- *Attributes field*—Specifies the valid operations and protection levels for operations that use this segment

There is also a *limit field*, not found in paged systems, which establishes the upper bound of valid offsets for this segment. [Figure B.26](#) shows examples of IA-32 segment descriptors.

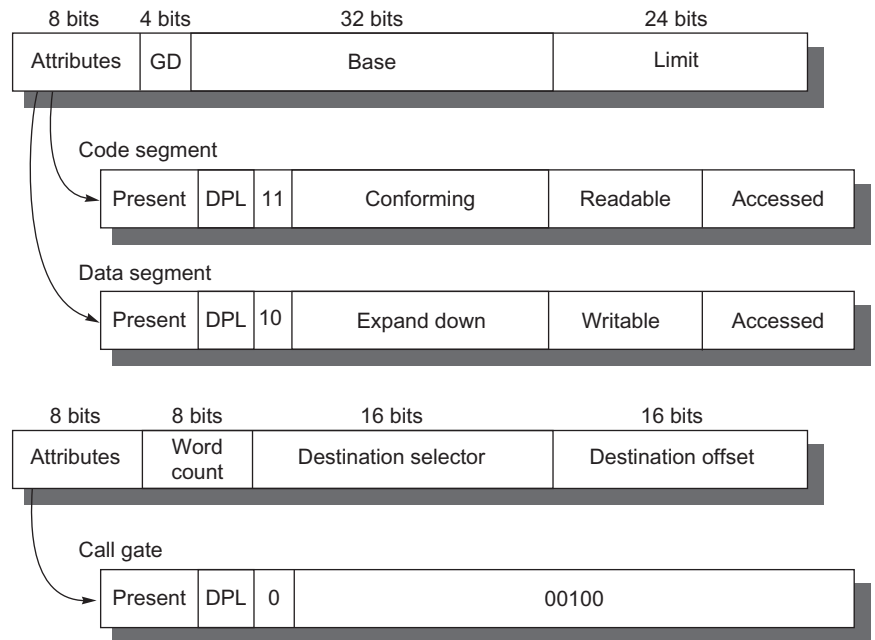

IA-32 provides an optional paging system in addition to this segmented addressing. The upper portion of the 32-bit address selects the segment descriptor, and the middle portion is an index into the page table selected by the descriptor. The following section describes the protection system that does not rely on paging.

### *Adding Sharing and Protection*

To provide for protected sharing, half of the address space is shared by all processes and half is unique to each process, called *global address space* and *local address space*, respectively. Each half is given a descriptor table with the appropriate name. A descriptor pointing to a shared segment is placed in the global descriptor table, while a descriptor for a private segment is placed in the local descriptor table.

A program loads an IA-32 segment register with an index to the table *and* a bit saying which table it desires. The operation is checked according to the attributes in the descriptor, the physical address being formed by adding the offset in the processor to the base in the descriptor, provided the offset is less than the limit field. Every segment descriptor has a separate 2-bit field to give the legal access level of this segment. A violation occurs only if the program tries to use a segment with a lower protection level in the segment descriptor.

We can now show how to invoke the payroll program mentioned herein to update the year-to-date information without allowing it to update salaries. The program could be given a descriptor to the information that has the writable field clear, meaning it can read but not write the data. A trusted program can then be supplied that will only write the year-to-date information. It is given a descriptor with the

**Figure B.26** The IA-32 segment descriptors are distinguished by bits in the attributes field. *Base*, *limit*, *present*, *readable*, and *writable* are all self-explanatory. *D* gives the default addressing size of the instructions: 16 bits or 32 bits. *G* gives the granularity of the segment limit: 0 means in bytes and 1 means in 4 KiB pages. *G* is set to 1 when paging is turned on to set the size of the page tables. *DPL* means *descriptor privilege level*—this is checked against the code privilege level to see if the access will be allowed. *Conforming* says the code takes on the privilege level of the code being called rather than the privilege level of the caller; it is used for library routines. The *expand-down* field flips the check to let the base field be the high-water mark and the limit field be the low-water mark. As you might expect, this is used for stack segments that grow down. *Word count* controls the number of words copied from the current stack to the new stack on a call gate. The other two fields of the call gate descriptor, *destination selector* and *destination offset*, select the descriptor of the destination of the call and the offset into it, respectively. There are many more than these three segment descriptors in the IA-32 protection model.

writable field set (Figure B.26). The payroll program invokes the trusted code using a code segment descriptor with the conforming field set. This setting means the called program takes on the privilege level of the code being called rather than the privilege level of the caller. Hence, the payroll program can read the salaries and call a trusted program to update the year-to-date totals, yet the payroll program cannot modify the salaries. If a Trojan horse exists in this system, to be effective it must be located in the trusted code whose only job is to update the year-to-date information. The argument for this style of protection is that limiting the scope of the vulnerability enhances security.

### *Adding Safe Calls from User to OS Gates and Inheriting Protection Level for Parameters*

Allowing the user to jump into the operating system is a bold step. How, then, can a hardware designer increase the chances of a safe system without trusting the operating system or any other piece of code? The IA-32 approach is to restrict where the user can enter a piece of code, to safely place parameters on the proper stack, and to make sure the user parameters don't get the protection level of the called code.

To restrict entry into others' code, the IA-32 provides a special segment descriptor, or *call gate*, identified by a bit in the attributes field. Unlike other descriptors, call gates are full physical addresses of an object in memory; the offset supplied by the processor is ignored. As stated previously, their purpose is to prevent the user from randomly jumping anywhere into a protected or more privileged code segment. In our programming example, this means the only place the payroll program can invoke the trusted code is at the proper boundary. This restriction is needed to make conforming segments work as intended.

What happens if caller and callee are "mutually suspicious," so that neither trusts the other? The solution is found in the word count field in the bottom descriptor in [Figure B.26](#). When a call instruction invokes a call gate descriptor, the descriptor copies the number of words specified in the descriptor from the local stack onto the stack corresponding to the level of this segment. This copying allows the user to pass parameters by first pushing them onto the local stack. The hardware then safely transfers them onto the correct stack. A return from a call gate will pop the parameters off both stacks and copy any return values to the proper stack. Note that this model is incompatible with the current practice of passing parameters in registers.

This scheme still leaves open the potential loophole of having the operating system use the user's address, passed as parameters, with the operating system's security level, instead of with the user's level. The IA-32 solves this problem by dedicating 2 bits in every processor segment register to the *requested protection level*. When an operating system routine is invoked, it can execute an instruction that sets this 2-bit field in all address parameters with the protection level of the user that called the routine. Thus, when these address parameters are loaded into the segment registers, they will set the requested protection level to the proper value. The IA-32 hardware then uses the requested protection level to prevent any foolishness: no segment can be accessed from the system routine using those parameters if it has a more privileged protection level than requested.

### **A Paged Virtual Memory Example: The 64-Bit Opteron Memory Management**

AMD engineers found few uses of the elaborate protection model described in the previous section. The popular model is a flat, 32-bit address space, introduced by the 80386, which sets all the base values of the segment registers to zero. Hence,

AMD dispensed with the multiple segments in the 64-bit mode. It assumes that the segment base is zero and ignores the limit field. The page sizes are 4 KiB, 2 MiB, and 4 MiB.

The 64-bit virtual address of the AMD64 architecture is mapped onto 52-bit physical addresses, although implementations can implement fewer bits to simplify hardware. The Opteron, for example, uses 48-bit virtual addresses and 40-bit physical addresses. AMD64 requires that the upper 16 bits of the virtual address be just the sign extension of the lower 48 bits, which it calls *canonical form*.

The size of page tables for the 64-bit address space is alarming. Hence, AMD64 uses a multilevel hierarchical page table to map the address space to keep the size reasonable. The number of levels depends on the size of the virtual address space. [Figure B.27](#) shows the four-level translation of the 48-bit virtual addresses of the Opteron.

The offsets for each of these page tables come from four 9-bit fields. Address translation starts with adding the first offset to the page-map level 4 base register and then reading memory from this location to get the base of the next-level page table. The next address offset is in turn added to this newly fetched address, and

**Figure B.27** The mapping of an Opteron virtual address. The Opteron virtual memory implementation with four page table levels supports an effective physical address size of 40 bits. Each page table has 512 entries, so each level field is 9 bits wide. The AMD64 architecture document allows the virtual address size to grow from the current 48 bits to 64 bits, and the physical address size to grow from the current 40 bits to 52 bits.

memory is accessed again to determine the base of the third page table. It happens again in the same fashion. The last address field is added to this final base address, and memory is read using this sum to (finally) get the physical address of the page being referenced. This address is concatenated with the 12-bit page offset to get the full physical address. Note that the page table in the Opteron architecture fits within a single 4 KiB page.

The Opteron uses a 64-bit entry in each of these page tables. The first 12 bits are reserved for future use, the next 52 bits contain the physical page frame number, and the last 12 bits give the protection and use information. Although the fields vary some between the page table levels, here are the basic ones:

- *Presence*—Says that page is present in memory.
- *Read/write*—Says whether page is read-only or read-write.
- *User/supervisor*—Says whether a user can access the page or if it is limited to the upper three privilege levels.
- *Dirty*—Says if page has been modified.
- *Accessed*—Says if page has been read or written since the bit was last cleared.
- *Page size*—Says whether the last level is for 4 KiB pages or 4 MiB pages; if it's the latter, then the Opteron only uses three instead of four levels of pages.
- *No execute*—Not found in the 80386 protection scheme, this bit was added to prevent code from executing in some pages.
- *Page level cache disable*—Says whether the page can be cached or not.
- *Page level write through*—Says whether the page allows write back or write through for data caches.

Because the Opteron usually goes through four levels of tables on a TLB miss, there are three potential places to check protection restrictions. The Opteron obeys only the bottom-level PTE, checking the others only to be sure the valid bit is set.

As the entry is 8 bytes long, each page table has 512 entries, and the Opteron has 4 KiB pages, the page tables are exactly one page long. Each of the four level fields are 9 bits long, and the page offset is 12 bits. This derivation leaves  $64 - (4 \times 9 + 12)$  or 16 bits to be sign extended to ensure canonical addresses.

Although we have explained translation of legal addresses, what prevents the user from creating illegal address translations and getting into mischief? The page tables themselves are protected from being written by user programs. Thus, the user can try any virtual address, but by controlling the page table entries the operating system controls what physical memory is accessed. Sharing of memory between processes is accomplished by having a page table entry in each address space point to the same physical memory page.

The Opteron employs four TLBs to reduce address translation time, two for instruction accesses and two for data accesses. Like multilevel caches, the Opteron

| Parameter          | Description                                                                                              |
|--------------------|----------------------------------------------------------------------------------------------------------|
| Block size         | 1 PTE (8 bytes)                                                                                          |
| L1 hit time        | 1 clock cycle                                                                                            |
| L2 hit time        | 7 clock cycles                                                                                           |
| L1 TLB size        | Same for instruction and data TLBs: 40 PTEs per TLBs, with 32 4 KiB pages and 8 for 2 MiB or 4 MiB pages |
| L2 TLB size        | Same for instruction and data TLBs: 512 PTEs of 4 KiB pages                                              |
| Block selection    | LRU                                                                                                      |
| Write strategy     | (Not applicable)                                                                                         |
| L1 block placement | Fully associative                                                                                        |
| L2 block placement | 4-way set associative                                                                                    |

**Figure B.28** Memory hierarchy parameters of the Opteron L1 and L2 instruction and data TLBs.

reduces TLB misses by having two larger L2 TLBs: one for instructions and one for data. [Figure B.28](#) describes the data TLB.

### Summary: Protection on the 32-Bit Intel Pentium Versus the 64-Bit AMD Opteron

Memory management in the Opteron is typical of most desktop or server computers today, relying on page-level address translation and correct operation of the operating system to provide safety to multiple processes sharing the computer. Although presented as alternatives, Intel has followed AMD’s lead and embraced the AMD64 architecture. Hence, both AMD and Intel support the 64-bit extension of 80x86; yet, for compatibility reasons, both support the elaborate segmented protection scheme.

If the segmented protection model looks harder to build than the AMD64 model, that’s because it is. This effort must be especially frustrating for the engineers, because few customers use the elaborate protection mechanism. In addition, the fact that the protection model is a mismatch to the simple paging protection of UNIX-like systems means it will be used only by someone writing an operating system especially for this computer, which hasn’t happened yet.

Even a review of memory hierarchy has fallacies and pitfalls!

**Pitfall** *Too small an address space.*

Just five years after DEC and Carnegie Mellon University collaborated to design the new PDP-11 computer family, it was apparent that their creation had a fatal

flaw. An architecture announced by IBM six years *before* the PDP-11 was still thriving, with minor modifications, 25 years later. And the DEC VAX, criticized for including unnecessary functions, sold millions of units after the PDP-11 went out of production. Why?

The fatal flaw of the PDP-11 was the size of its addresses (16 bits) as compared with the address sizes of the IBM 360 (24–31 bits) and the VAX (32 bits). Address size limits the program length, because the size of a program and the amount of data needed by the program must be less than  $2^{\text{Address size}}$ . The reason the address size is so hard to change is that it determines the minimum width of anything that can contain an address: PC, register, memory word, and effective-address arithmetic. If there is no plan to expand the address from the start, then the chances of successfully changing address size are so slim that it usually means the end of that computer family. [Bell and Strecker \(1976\)](#) put it like this:

There is only one mistake that can be made in computer design that is difficult to recover from—not having enough address bits for memory addressing and memory management. The PDP-11 followed the unbroken tradition of nearly every known computer. [p. 2]

A partial list of successful computers that eventually starved to death for lack of address bits includes the PDP-8, PDP-10, PDP-11, Intel 8080, Intel 8086, Intel 80186, Intel 80286, Motorola 6800, AMI 6502, Zilog Z80, CRAY-1, and CRAY X-MP.

The venerable 80x86 line bears the distinction of having been extended twice, first to 32 bits with the Intel 80386 in 1985 and recently to 64 bits with the AMD Opteron.

**Pitfall** *Ignoring the impact of the operating system on the performance of the memory hierarchy.*

[Figure B.29](#) shows the memory stall time due to the operating system spent on three large workloads. About 25% of the stall time is either spent in misses in the operating system or results from misses in the application programs because of interference with the operating system.

**Pitfall** *Relying on the operating systems to change the page size over time.*

The Alpha architects had an elaborate plan to grow the architecture over time by growing its page size, even building it into the size of its virtual address. When it came time to grow page sizes with later Alphas, the operating system designers balked and the virtual memory system was revised to grow the address space while maintaining the 8 KiB page.

Architects of other computers noticed very high TLB miss rates, and so added multiple, larger page sizes to the TLB. The hope was that operating systems programmers would allocate an object to the largest page that made sense, thereby preserving TLB entries. After a decade of trying, most operating systems use these “superpages” only for handpicked functions: mapping the display memory or other I/O devices, or using very large pages for the database code.

| Workload | Time              |         |                                  |                                |                                  |                           |                                 |                   |                                            |
|----------|-------------------|---------|----------------------------------|--------------------------------|----------------------------------|---------------------------|---------------------------------|-------------------|--------------------------------------------|
|          | Misses            |         | % Time due to application misses |                                | % Time due directly to OS misses |                           |                                 |                   | % Time OS misses and application conflicts |
|          | % in applications | % in OS | Inherent application misses      | OS conflicts with applications | OS instruction misses            | Data misses for migration | Data misses in block operations | Rest of OS misses |                                            |

## B.7

## Concluding Remarks

The difficulty of building a memory system to keep pace with faster processors is underscored by the fact that the raw material for main memory is the same as that found in the cheapest computer. It is the principle of locality that helps us here—its soundness is demonstrated at all levels of the memory hierarchy in current computers, from disks to TLBs.

However, the increasing relative latency to memory, taking hundreds of clock cycles in 2016, means that programmers and compiler writers must be aware of the parameters of the caches and TLBs if they want their programs to perform well.

## B.8

## Historical Perspective and References

In Section M.3 (available online) we examine the history of caches, virtual memory, and virtual machines. (The historical section covers both this appendix and [Chapter 3](#).) IBM plays a prominent role in the history of all three. References for further reading are included.

## Exercises by Amr Zaky

- B.1 [10/10/10/15] <B.1> You are trying to appreciate how important the principle of locality is in justifying the use of a cache memory, so you experiment with a computer having an L1 data cache and a main memory (you exclusively focus on data accesses). The latencies (in CPU cycles) of the different kinds of accesses are as follows: cache hit, 1 cycle; cache miss, 110 cycles; main memory access with cache disabled, 105 cycles.
- a. [10] <B.1> When you run a program with an overall miss rate of 3%, what will the average memory access time (in CPU cycles) be?
  - b. [10] <B.1> Next, you run a program specifically designed to produce completely random data addresses with no locality. Toward that end, you use an array of size 1 GB (all of which fits in the main memory). Accesses to random elements of this array are continuously made (using a uniform random number generator to generate the elements indices). If your data cache size is 64 KB, what will the average memory access time be?
  - c. [10] <B.1> If you compare the result obtained in part (b) with the main memory access time when the cache is disabled, what can you conclude about the role of the principle of locality in justifying the use of cache memory?
  - d. [15] <B.1> You observed that a cache hit produces a gain of 104 cycles (1 cycle vs. 105), but it produces a loss of 5 cycles in the case of a miss (110 cycles vs. 105). In the general case, we can express these two quantities as G (gain) and L (loss). Using these two quantities (G and L), identify the highest miss rate after which the cache use would be disadvantageous.
- B.2 [15/15] <B.1> For the purpose of this exercise, we assume that we have a 512-byte cache with 64-byte blocks. We will also assume that the main memory is 2 KB large. We can regard the memory as an array of 64-byte blocks: M0, M1, ..., M31. [Figure B.30](#) sketches the memory blocks that can reside in different cache blocks if the cache was direct-mapped.
- a. [15] <B.1> Show the contents of the table if the cache is organized as a fully-associative cache.
  - b. [15] <B.1> Repeat part (a) with the cache organized as a four-way set associative cache.
- B.3 [10/10/10/10/15/10/15/20] <B.1> Cache organization is often influenced by the desire to reduce the cache's power consumption. For that purpose we assume that the cache is physically distributed into a data array (holding the data), a tag array (holding the tags), and replacement array (holding information needed by replacement policy). Furthermore, every one of these arrays is physically distributed into multiple subarrays (one per way) that can be individually accessed; for example, a four-way set associative least recently used (LRU) cache would have four data subarrays, four tag subarrays, and four replacement subarrays. We assume that the

| Cache block | Set | Way | Possible memory blocks |
|-------------|-----|-----|------------------------|
| 0           | 0   | 0   | M0, M8, M16, M24       |
| 1           | 1   | 0   | M1, M9, M17, M25       |
| 2           | 2   | 0   | M2, M10, M18, M26      |
| 3           | 3   | 0   | ....                   |
| 4           | 4   | 0   | ....                   |
| 5           | 5   | 0   | ....                   |
| 6           | 6   | 0   | ....                   |
| 7           | 7   | 0   | M7, M15, M23, M31      |

**Figure B.30** Memory blocks distributed to direct-mapped cache.

| Array               | Power consumption weight<br>(per way accessed) |
|---------------------|------------------------------------------------|
| Data array          | 20 units                                       |
| Tag                 | Array 5 units                                  |
| Miscellaneous array | 1 unit                                         |
| Memory access       | 200 units                                      |

**Figure B.31** Power consumption costs of different operations.

replacement subarrays are accessed once per access when the LRU replacement policy is used, and once per miss if the first-in, first-out (FIFO) replacement policy is used. It is not needed when a random replacement policy is used. For a specific cache, it was determined that the accesses to the different arrays have the following power consumption weights (Figure B.31):

- [10] <B.1> A cache read hit. All arrays are read simultaneously.
- [10] <B.1> Repeat part (a) for a cache read miss.
- [10] <B.1> Repeat part (a) assuming that the cache access is split across two cycles. In the first cycle, all the tag subarrays are accessed. In the second cycle, only the subarray whose tag matched will be accessed.
- [10] <B.1> Repeat part (c) for a cache read miss (no data array accesses in the second cycle).
- [15] <B.1> Repeat part (c) assuming that logic is added to predict the cache way to be accessed. Only the tag subarray for the predicted way is accessed in cycle one. A way hit (address match in predicted way) implies a cache hit. A way miss dictates examining all the tag subarrays in the second cycle. In case of a way hit, only one data subarray (the one whose tag matched) is accessed in cycle two. Assume the way predictor hits.

f. [10] <B.1> Repeat part (e) assuming that the way predictor misses (the way it choses is wrong). When it fails, the way predictor adds an extra cycle in which it accesses all the tag subarrays. Assume the way predictor miss is followed by a cache read hit.

g. [15] <B.1> Repeat part (f) assuming a cache read miss.

h. [20] <B.1> Use parts (e), (f), and (g) for the general case where the workload has the following statistics: way predictor miss rate=5% and cache miss rate=3%. (Consider different replacement policies.)

Estimate the memory system (cache+memory) power usage (in power units) for the following configurations. We assume the cache is four-way set associative. Provide answers for the LRU, FIFO, and random replacement policies.

B.4 [10/10/15/15/15/20] <B.1> We compare the write bandwidth requirements of write-through versus write-back caches using a concrete example. Let us assume that we have a 64 KB cache with a line size of 32 bytes. The cache will allocate a line on a write miss. If configured as a write-back cache, it will write back all of the dirty line if it needs to be replaced. We will also assume that the cache is connected to the lower level in the hierarchy through a 64-bit-wide (8-byte-wide) bus. The number of CPU cycles for a B-bytes write access on this bus is

$10 + 5 \lceil \frac{B}{8} - 1 \rceil$ , where the square brackets represent the “ceiling” function. For example, an 8-byte write would take

$10 + 5 \lceil \frac{8}{8} - 1 \rceil = 10$  cycles, whereas using the same formula a 12-byte write would take 15 cycles.

Answer the following questions while referring to the C code snippet below:

```
... #define PORTION 1
...
 base = 8*i;
 for (unsigned int j = base; j < base + PORTION; j++)
//assume j is stored in a register
 {
 data[j] = j;
 }
```

a. [10] <B.1> For a write-through cache, how many CPU cycles are spent on write transfers to the memory for all the combined iterations of the j loop?

b. [10] <B.1> If the cache is configured as a write-back cache, how many CPU cycles are spent on writing back a cache line?

c. [15] <B.1> Change PORTION to 8 and repeat part (a).

d. [15] <B.1> What is the minimum number of array updates to the same cache line (before replacing it) that would render the write-back cache superior?

e. [15] <B.1> Think of a scenario where all the words of the cache line will be written (not necessarily using the above code) and a write-through cache will require fewer total CPU cycles than the write-back cache.

- B.5 [10/10/10/10] <B.2> You are building a system around a processor with in-order execution that runs at 1.1 GHz and has a CPI of 1.35 excluding memory accesses. The only instructions that read or write data from memory are loads (20% of all instructions) and stores (10% of all instructions). The memory system for this computer is composed of a split L1 cache that imposes no penalty on hits. Both the I-cache and D-cache are direct-mapped and hold 32 KB each. The I-cache has a 2% miss rate and 32-byte blocks, and the D-cache is write-through with a 5% miss rate and 16-byte blocks. There is a write buffer on the D-cache that eliminates stalls for 95% of all writes. The 512 KB write-back, unified L2 cache has 64-byte blocks and an access time of 15 ns. It is connected to the L1 cache by a 128-bit data bus that runs at 266 MHz and can transfer one 128-bit word per bus cycle. Of all memory references sent to the L2 cache in this system, 80% are satisfied without going to main memory. Also, 50% of all blocks replaced are dirty. The 128-bit-wide main memory has an access latency of 60 ns, after which any number of bus words may be transferred at the rate of one per cycle on the 128-bit-wide 133 MHz main memory bus.
- [10] <B.2> What is the average memory access time for instruction accesses?
  - [10] <B.2> What is the average memory access time for data reads?
  - [10] <B.2> What is the average memory access time for data writes?
  - [10] <B.2> What is the overall CPI, including memory accesses?
- B.6 [10/15/15] <B.2> Converting miss rate (misses per reference) into misses per instruction relies upon two factors: references per instruction fetched and the fraction of fetched instructions that actually commits.
- [10] <B.2> The formula for misses per instruction on page B-5 is written first in terms of three factors: miss rate, memory accesses, and instruction count. Each of these factors represents actual events. What is different about writing misses per instruction as *miss rate* times the factor *memory accesses per instruction*?
  - [15] <B.2> Speculative processors will fetch instructions that do not commit. The formula for misses per instruction on page B-5 refers to misses per instruction on the execution path; that is, only the instructions that must actually be executed to carry out the program. Convert the formula for misses per instruction on page B-5 into one that uses only miss rate, references per instruction fetched, and fraction of fetched instructions that commit. Why rely upon these factors rather than those in the formula on page B-5?
  - [15] <B.2> The conversion in part (b) could yield an incorrect value to the extent that the value of the factor references per instruction fetched is not equal to the number of references for any particular instruction. Rewrite the formula of part (b) to correct this deficiency.
- B.7 [20] <B.1, B.3> In systems with a write-through L1 cache backed by a write-back L2 cache instead of main memory, a merging write buffer can be simplified. Explain how this can be done. Are there situations where having a full write buffer (instead of the simple version you have just proposed) could be helpful?

B.8 [5/5/5] <B.3> We want to observe the following calculation

$$d_i = a_i + b_i * c_i, \quad i : (0 : 511)$$

Arrays *a*, *b*, *c*, and *d* memory layout is displayed below (each has 512 4-byte-wide integer elements).

The above calculation employs a for loop that runs through 512 iterations.

Assume a 32 Kbyte 4-way set associative cache with a single cycle access time. The miss penalty is 100 CPU cycles/access, and so is the cost of a write-back. The cache is a write-back on hits write-allocate on misses cache (Figure B.32).

- a. [5] <B3> How many cycles will an iteration take if all three loads and single store miss in the data cache?
  - b. [5] <B3> If the cache line size is 16 bytes, what is the average number of cycles an average iteration will take? (Hint: Spatial locality!)
  - c. [5] <B3> If the cache line size is 64 bytes, what is the average number of cycles an average iteration will take?
  - d. If the cache is direct-mapped and its size is reduced to 2048 bytes, what is the average number of cycles an average iteration will take?
- B.9 [20] <B.3> Increasing a cache's associativity (with all other parameters kept constant) statistically reduces the miss rate. However, there can be pathological cases where increasing a cache's associativity would increase the miss rate for a particular workload.

Consider the case of direct-mapped compared to a two-way set associative cache of equal size. Assume that the set associative cache uses the LRU replacement policy. To simplify, assume that the block size is one word. Now, construct a trace of word accesses that would produce more misses in the two-way associative cache.

(Hint: Focus on constructing a trace of accesses that are exclusively directed to a single set of the two-way set associative cache, such that the same trace would exclusively access two blocks in the direct-mapped cache.)

- B.10 [10/10/15] <B.3> Consider a two-level memory hierarchy made of L1 and L2 data caches. Assume that both caches use write-back policy on write hit and both have the same block size. List the actions taken in response to the following events:
- a. [10] <B.3> An L1 cache miss when the caches are organized in an inclusive hierarchy.

| Mem. address in bytes | Contents       |

| 10                    |                   |                           |
| 6                     |                   |                           |
| 15                    |                   |                           |
| 12                    |                   |                           |
| 7                     |                   |                           |
| 2                     |                   |                           |

**Figure B.35** Page access trace.

- c. [15] <B.4> Are there page table structures that would be difficult to handle in hardware but possible in software? Are there any such structures that would be difficult for software to handle but easy for hardware to manage?
- d. [15] <B.4> Why are TLB miss rates for floating-point programs generally higher than those for integer programs?

- B.15 [20/20] <B.5> It is possible to provide more flexible protection than that in the Intel Pentium architecture by using a protection scheme similar to that used in the Hewlett-Packard Precision Architecture (HP/PA). In such a scheme, each page table entry contains a “protection ID” (key) along with access rights for the page. On each reference, the CPU compares the protection ID in the page table entry with those stored in each of four protection ID registers (access to these registers requires that the CPU be in supervisor mode). If there is no match for the protection ID in the page table entry or if the access is not a permitted access (writing to a read-only page, for example), an exception is generated.
- a. [20] <B.5> Explain how this model could be used to facilitate the construction of operating systems from relatively small pieces of code that cannot overwrite each other (microkernels). What advantages might such an operating system have over a monolithic operating system in which any code in the OS can write to any memory location?
  - b. [20] <B.5> A simple design change to this system would allow two protection IDs for each page table entry, one for read access and the other for either write or execute access (the field is unused if neither the writable nor executable bit is set). What advantages might there be from having different protection IDs for read and write capabilities? (*Hint*: Could this make it easier to share data and code between processes?)

# Pipelining: Basic and Intermediate Concepts

It is quite a three-pipe problem.

Sir Arthur Conan Doyle,  
*The Adventures of Sherlock Holmes*

## C.1

**Introduction**

Many readers of this text will have covered the basics of pipelining in another text (such as our more basic text *Computer Organization and Design*) or in another course. Because [Chapter 3](#) builds heavily on this material, readers should ensure that they are familiar with the concepts discussed in this appendix before proceeding. As you read [Chapter 3](#), you may find it helpful to turn to this material for a quick review.

We begin the appendix with the basics of pipelining, including discussing the data path implications, introducing hazards, and examining the performance of pipelines. This section describes the basic five-stage RISC pipeline that is the basis for the rest of the appendix. [Section C.2](#) describes the issue of hazards, why they cause performance problems, and how they can be dealt with. [Section C.3](#) discusses how the simple five-stage pipeline is actually implemented, focusing on control and how hazards are dealt with.

[Section C.4](#) discusses the interaction between pipelining and various aspects of instruction set design, including discussing the important topic of exceptions and their interaction with pipelining. Readers unfamiliar with the concepts of precise and imprecise interrupts and resumption after exceptions will find this material useful, because they are key to understanding the more advanced approaches in [Chapter 3](#).

[Section C.5](#) discusses how the five-stage pipeline can be extended to handle longer-running floating-point instructions. [Section C.6](#) puts these concepts together in a case study of a deeply pipelined processor, the MIPS R4000/4400, including both the eight-stage integer pipeline and the floating-point pipeline. The MIPS R4000 is similar to a single-issue embedded processor, such as the ARM Cortex-A5, which became available in 2010, and was used in several smart phones and tablets.

[Section C.7](#) introduces the concept of dynamic scheduling and the use of scoreboards to implement dynamic scheduling. It is introduced as a cross-cutting issue, because it can be used to serve as an introduction to the core concepts in [Chapter 3](#), which focused on dynamically scheduled approaches. [Section C.7](#) is also a gentle introduction to the more complex Tomasulo's algorithm covered in [Chapter 3](#). Although Tomasulo's algorithm can be covered and understood without introducing scoreboarding, the scoreboarding approach is simpler and easier to comprehend.

**What Is Pipelining?**

*Pipelining* is an implementation technique whereby multiple instructions are overlapped in execution; it takes advantage of parallelism that exists among the actions needed to execute an instruction. Today, pipelining is the key implementation technique used to make fast processors, and even processors that cost less than a dollar are pipelined.

A pipeline is like an assembly line. In an automobile assembly line, there are many steps, each contributing something to the construction of the car. Each step operates in parallel with the other steps, although on a different car. In a computer pipeline, each step in the pipeline completes a part of an instruction. Like the assembly line, different steps are completing different parts of different instructions in parallel. Each of these steps is called a *pipe stage* or a *pipe segment*. The stages are connected one to the next to form a pipe—instructions enter at one end, progress through the stages, and exit at the other end, just as cars would in an assembly line.

In an automobile assembly line, *throughput* is defined as the number of cars per hour and is determined by how often a completed car exits the assembly line. Likewise, the throughput of an instruction pipeline is determined by how often an instruction exits the pipeline. Because the pipe stages are hooked together, all the stages must be ready to proceed at the same time, just as we would require in an assembly line. The time required between moving an instruction one step down the pipeline is a *processor cycle*. Because all stages proceed at the same time, the length of a processor cycle is determined by the time required for the slowest pipe stage, just as in an auto assembly line the longest step would determine the time between advancing cars in the line. In a computer, this processor cycle is almost always 1 clock cycle.

The pipeline designer's goal is to balance the length of each pipeline stage, just as the designer of the assembly line tries to balance the time for each step in the process. If the stages are perfectly balanced, then the time per instruction on the pipelined processor—assuming ideal conditions—is equal to

$$\frac{\text{Time per instruction on unpipelined machine}}{\text{Number of pipe stages}}$$

Under these conditions, the speedup from pipelining equals the number of pipe stages, just as an assembly line with  $n$  stages can ideally produce cars  $n$  times as fast. Usually, however, the stages will not be perfectly balanced; furthermore, pipelining does involve some overhead. Thus, the time per instruction on the pipelined processor will not have its minimum possible value, yet it can be close.

Pipelining yields a reduction in the average execution time per instruction. If the starting point is a processor that takes multiple clock cycles per instruction, then pipelining reduces the CPI. This is the primary view we will take.

Pipelining is an implementation technique that exploits parallelism among the instructions in a sequential instruction stream. It has the substantial advantage that, unlike some speedup techniques (see [Chapter 4](#)), it is not visible to the programmer.

## The Basics of the RISC V Instruction Set

Throughout this book we use RISC V, a load-store architecture, to illustrate the basic concepts. Nearly all the ideas we introduce in this book are applicable to other

processors, but the implementation may be much more complicated with complex instructions. In this section, we make use of the core of the RISC V architecture; see [Chapter 1](#) for a full description. Although we use RISC V, the concepts are significantly similar in that they will apply to any RISC, including the core architectures of ARM and MIPS. All RISC architectures are characterized by a few key properties:

- All operations on data apply to data in registers and typically change the entire register (32 or 64 bits per register).
- The only operations that affect memory are load and store operations that move data from memory to a register or to memory from a register, respectively. Load and store operations that load or store less than a full register (e.g., a byte, 16 bits, or 32 bits) are often available.
- The instruction formats are few in number, with all instructions typically being one size. In RISC V, the register specifiers: rs1, rs2, and rd are always in the same place simplifying the control.

These simple properties lead to dramatic simplifications in the implementation of pipelining, which is why these instruction sets were designed this way. [Chapter 1](#) contains a full description of the RISC V ISA, and we assume the reader has read [Chapter 1](#).

## A Simple Implementation of a RISC Instruction Set

To understand how a RISC instruction set can be implemented in a pipelined fashion, we need to understand how it is implemented *without* pipelining. This section shows a simple implementation where every instruction takes at most 5 clock cycles. We will extend this basic implementation to a pipelined version, resulting in a much lower CPI. Our unpipelined implementation is not the most economical or the highest-performance implementation without pipelining. Instead, it is designed to lead naturally to a pipelined implementation. Implementing the instruction set requires the introduction of several temporary registers that are not part of the architecture; these are introduced in this section to simplify pipelining. Our implementation will focus only on a pipeline for an integer subset of a RISC architecture that consists of load-store word, branch, and integer ALU operations.

Every instruction in this RISC subset can be implemented in, at most, 5 clock cycles. The 5 clock cycles are as follows.

### 1. *Instruction fetch cycle* (IF):

Send the program counter (PC) to memory and fetch the current instruction from memory. Update the PC to the next sequential instruction by adding 4 (because each instruction is 4 bytes) to the PC.

## 2. *Instruction decode/register fetch cycle (ID):*

Decode the instruction and read the registers corresponding to register source specifiers from the register file. Do the equality test on the registers as they are read, for a possible branch. Sign-extend the offset field of the instruction in case it is needed. Compute the possible branch target address by adding the sign-extended offset to the incremented PC.

Decoding is done in parallel with reading registers, which is possible because the register specifiers are at a fixed location in a RISC architecture. This technique is known as *fixed-field decoding*. Note that we may read a register we don't use, which doesn't help but also doesn't hurt performance. (It does waste energy to read an unneeded register, and power-sensitive designs might avoid this.) For loads and ALU immediate operations, the immediate field is always in the same place, so we can easily sign extend it. (For a more complete implementation of RISC V, we would need to compute two different sign-extended values, because the immediate field for store is in a different location.)

## 3. *Execution/effective address cycle (EX):*

The ALU operates on the operands prepared in the prior cycle, performing one of three functions, depending on the instruction type.

- Memory reference—The ALU adds the base register and the offset to form the effective address.
- Register-Register ALU instruction—The ALU performs the operation specified by the ALU opcode on the values read from the register file.
- Register-Immediate ALU instruction—The ALU performs the operation specified by the ALU opcode on the first value read from the register file and the sign-extended immediate.
- Conditional branch—Determine whether the condition is true.

In a load-store architecture the effective address and execution cycles can be combined into a single clock cycle, because no instruction needs to simultaneously calculate a data address and perform an operation on the data.

## 4. *Memory access (MEM):*

If the instruction is a load, the memory does a read using the effective address computed in the previous cycle. If it is a store, then the memory writes the data from the second register read from the register file using the effective address.

## 5. *Write-back cycle (WB):*

- Register-Register ALU instruction or load instruction:

Write the result into the register file, whether it comes from the memory system (for a load) or from the ALU (for an ALU instruction).

In this implementation, branch instructions require three cycles, store instructions require four cycles, and all other instructions require five cycles. Assuming a

branch frequency of 12% and a store frequency of 10%, a typical instruction distribution leads to an overall CPI of 4.66. This implementation, however, is not optimal either in achieving the best performance or in using the minimal amount of hardware given the performance level; we leave the improvement of this design as an exercise for you and instead focus on pipelining this version.

The Classic Five-Stage Pipeline for a RISC Processor

We can pipeline the execution described in the previous section with almost no changes by simply starting a new instruction on each clock cycle. (See why we chose this design?) Each of the clock cycles from the previous section becomes a *pipe stage*—a cycle in the pipeline. This results in the execution pattern shown in Figure C.1, which is the typical way a pipeline structure is drawn. Although each instruction takes 5 clock cycles to complete, during each clock cycle the hardware will initiate a new instruction and will be executing some part of the five different instructions.

You may find it hard to believe that pipelining is as simple as this; it’s not. In this and the following sections, we will make our RISC pipeline “real” by dealing with problems that pipelining introduces.

To start with, we have to determine what happens on every clock cycle of the processor and make sure we don’t try to perform two different operations with the same data path resource on the same clock cycle. For example, a single ALU cannot be asked to compute an effective address and perform a subtract operation at the same time. Thus, we must ensure that the overlap of instructions in the pipeline cannot cause such a conflict. Fortunately, the simplicity of a RISC instruction set makes resource evaluation relatively easy. Figure C.2 shows a simplified version of a RISC data path drawn in pipeline fashion. As you can see, the major functional units are used in different cycles, and hence overlapping the execution of multiple

| Instruction number       | Clock number |    |    |     |     |     |     |     |    |
|--------------------------|--------------|----|----|-----|-----|-----|-----|-----|----|
|                          | 1            | 2  | 3  | 4   | 5   | 6   | 7   | 8   | 9  |
| Instruction <i>i</i>     | IF           | ID | EX | MEM | WB  |     |     |     |    |
| Instruction <i>i</i> + 1 |              | IF | ID | EX  | MEM | WB  |     |     |    |
| Instruction <i>i</i> + 2 |              |    | IF | ID  | EX  | MEM | WB  |     |    |
| Instruction <i>i</i> + 3 |              |    |    | IF  | ID  | EX  | MEM | WB  |    |
| Instruction <i>i</i> + 4 |              |    |    |     | IF  | ID  | EX  | MEM | WB |

**Figure C.1 Simple RISC pipeline.** On each clock cycle, another instruction is fetched and begins its five-cycle execution. If an instruction is started every clock cycle, the performance will be up to five times that of a processor that is not pipelined. The names for the stages in the pipeline are the same as those used for the cycles in the unpipelined implementation: IF = instruction fetch, ID = instruction decode, EX = execution, MEM = memory access, and WB = write-back.

**Figure C.2** The pipeline can be thought of as a series of data paths shifted in time. This figure shows the overlap among the parts of the data path, with clock cycle 5 (CC 5) showing the steady-state situation. Because the register file is used as a source in the ID stage and as a destination in the WB stage, it appears twice. We show that it is read in one part of the stage and written in another by using a solid line, on the right or left, respectively, and a dashed line on the other side. The abbreviation IM is used for instruction memory, DM for data memory, and CC for clock cycle.

instructions introduces relatively few conflicts. There are three observations on which this fact rests.

First, we use separate instruction and data memories, which we would typically implement with separate instruction and data caches (discussed in [Chapter 2](#)). The use of separate caches eliminates a conflict for a single memory that would arise between instruction fetch and data memory access. Notice that if our pipelined processor has a clock cycle that is equal to that of the unpipelined version, the memory system must deliver five times the bandwidth. This increased demand is one cost of higher performance.

Second, the register file is used in the two stages: one for reading in ID and one for writing in WB. These uses are distinct, so we simply show the register file in two places. Hence, we need to perform two reads and one write every clock cycle.

To handle reads and a write to the same register (and for another reason, which will become obvious shortly), we perform the register write in the first half of the clock cycle and the read in the second half.

Third, [Figure C.2](#) does not deal with the PC. To start a new instruction every clock, we must increment and store the PC every clock, and this must be done during the IF stage in preparation for the next instruction. Furthermore, we must also have an adder to compute the potential branch target address during ID. One further problem is that we need the ALU in the ALU stage to evaluate the branch condition. Actually, we don't really need a full ALU to evaluate the comparison between two registers, but we need enough of the function that it has to occur in this pipestage.

Although it is critical to ensure that instructions in the pipeline do not attempt to use the hardware resources at the same time, we must also ensure that instructions in different stages of the pipeline do not interfere with one another. This separation is done by introducing *pipeline registers* between successive stages of the pipeline, so that at the end of a clock cycle all the results from a given stage are stored into a register that is used as the input to the next stage on the next clock cycle. [Figure C.3](#) shows the pipeline drawn with these pipeline registers.

Although many figures will omit such registers for simplicity, they are required to make the pipeline operate properly and must be present. Of course, similar registers would be needed even in a multicycle data path that had no pipelining (because only values in registers are preserved across clock boundaries). In the case of a pipelined processor, the pipeline registers also play the key role of carrying intermediate results from one stage to another where the source and destination may not be directly adjacent. For example, the register value to be stored during a store instruction is read during ID, but not actually used until MEM; it is passed through two pipeline registers to reach the data memory during the MEM stage. Likewise, the result of an ALU instruction is computed during EX, but not actually stored until WB; it arrives there by passing through two pipeline registers. It is sometimes useful to name the pipeline registers, and we follow the convention of naming them by the pipeline stages they connect, so the registers are called IF/ID, ID/EX, EX/MEM, and MEM/WB.

## Basic Performance Issues in Pipelining

Pipelining increases the processor instruction throughput—the number of instructions completed per unit of time—but it does not reduce the execution time of an individual instruction. In fact, it usually slightly increases the execution time of each instruction due to overhead in the control of the pipeline. The increase in instruction throughput means that a program runs faster and has lower total execution time, even though no single instruction runs faster!

The fact that the execution time of each instruction does not decrease puts limits on the practical depth of a pipeline, as we will see in the next section. In addition to limitations arising from pipeline latency, limits arise from imbalance

**Figure C.3** A pipeline showing the pipeline registers between successive pipeline stages. Notice that the registers prevent interference between two different instructions in adjacent stages in the pipeline. The registers also play the critical role of carrying data for a given instruction from one stage to the other. The edge-triggered property of registers—that is, that the values change instantaneously on a clock edge—is critical. Otherwise, the data from one instruction could interfere with the execution of another!

among the pipe stages and from pipelining overhead. Imbalance among the pipe stages reduces performance because the clock can run no faster than the time needed for the slowest pipeline stage. Pipeline overhead arises from the combination of pipeline register delay and clock skew. The pipeline registers add setup time, which is the time that a register input must be stable before the clock signal that triggers a write occurs, plus propagation delay to the clock cycle. Clock skew, which is the maximum delay between when the clock arrives at any two registers,

also contributes to the lower limit on the clock cycle. Once the clock cycle is as small as the sum of the clock skew and latch overhead, no further pipelining is useful, because there is no time left in the cycle for useful work. The interested reader should see [Kunkel and Smith \(1986\)](#).

---

**Example** Consider the unpipelined processor in the previous section. Assume that it has a 4 GHz clock (or a 0.5 ns clock cycle) and that it uses four cycles for ALU operations and branches and five cycles for memory operations. Assume that the relative frequencies of these operations are 40%, 20%, and 40%, respectively. Suppose that due to clock skew and setup, pipelining the processor adds 0.1 ns of overhead to the clock. Ignoring any latency impact, how much speedup in the instruction execution rate will we gain from a pipeline?

**Answer** The average instruction execution time on the unpipelined processor is

$$\begin{aligned}\text{Average instruction execution time} &= \text{Clock cycle} \times \text{Average CPI} \\ &= 0.5 \text{ ns} \times [(40\% + 20\%) \times 4 + 40\% \times 5] \\ &= 0.5 \text{ ns} \times 4.4 \\ &= 2.2 \text{ ns}\end{aligned}$$

In the pipelined implementation, the clock must run at the speed of the slowest stage plus overhead, which will be 0.5 + 0.1 or 0.6 ns; this is the average instruction execution time. Thus, the speedup from pipelining is

$$\begin{aligned}\text{Speedup from pipelining} &= \frac{\text{Average instruction time unpipelined}}{\text{Average instruction time pipelined}} \\ &= \frac{2.2 \text{ ns}}{0.6 \text{ ns}} = 3.7 \text{ times}\end{aligned}$$

The 0.1 ns overhead essentially establishes a limit on the effectiveness of pipelining. If the overhead is not affected by changes in the clock cycle, Amdahl's Law tells us that the overhead limits the speedup.

---

This simple RISC pipeline would function just fine for integer instructions if every instruction were independent of every other instruction in the pipeline. In reality, instructions in the pipeline can depend on one another; this is the topic of the next section.

## C.2

### The Major Hurdle of Pipelining—Pipeline Hazards

There are situations, called *hazards*, that prevent the next instruction in the instruction stream from executing during its designated clock cycle. Hazards reduce the performance from the ideal speedup gained by pipelining. There are three classes of hazards:

1. *Structural hazards* arise from resource conflicts when the hardware cannot support all possible combinations of instructions simultaneously in overlapped execution. In modern processors, structural hazards occur primarily in special purpose functional units that are less frequently used (such as floating point divide or other complex long running instructions). They are not a major performance factor, assuming programmers and compiler writers are aware of the lower throughput of these instructions. Instead of spending more time on this infrequent case, we focus on the two other hazards that are much more frequent.
2. *Data hazards* arise when an instruction depends on the results of a previous instruction in a way that is exposed by the overlapping of instructions in the pipeline.
3. *Control hazards* arise from the pipelining of branches and other instructions that change the PC.

Hazards in pipelines can make it necessary to *stall* the pipeline. Avoiding a hazard often requires that some instructions in the pipeline be allowed to proceed while others are delayed. For the pipelines we discuss in this appendix, when an instruction is stalled, all instructions issued *later* than the stalled instruction—and hence not as far along in the pipeline—are also stalled. Instructions issued *earlier* than the stalled instruction—and hence farther along in the pipeline—must continue, because otherwise the hazard will never clear. As a result, no new instructions are fetched during the stall. We will see several examples of how pipeline stalls operate in this section—don't worry, they aren't as complex as they might sound!

## Performance of Pipelines With Stalls

A stall causes the pipeline performance to degrade from the ideal performance. Let's look at a simple equation for finding the actual speedup from pipelining, starting with the formula from the previous section:

$$\begin{aligned}
 \text{Speedup from pipelining} &= \frac{\text{Average instruction time unpipelined}}{\text{Average instruction time pipelined}} \\
 &= \frac{\text{CPI unpipelined} \times \text{Clock cycle unpipelined}}{\text{CPI pipelined} \times \text{Clock cycle pipelined}} \\
 &= \frac{\text{CPI unpipelined} \times \text{Clock cycle unpipelined}}{\text{CPI pipelined} \times \text{Clock cycle pipelined}}
 \end{aligned}$$

Pipelining can be thought of as decreasing the CPI or the clock cycle time. Because it is traditional to use the CPI to compare pipelines, let's start with that assumption. The ideal CPI on a pipelined processor is almost always 1. Hence, we can compute the pipelined CPI:

$$\begin{aligned}
 \text{CPI pipelined} &= \text{Ideal CPI} + \text{Pipeline stall clock cycles per instruction} \\
 &= 1 + \text{Pipelines stall clock cycles per instruction}
 \end{aligned}$$

If we ignore the cycle time overhead of pipelining and assume that the stages are perfectly balanced, then the cycle time of the two processors can be equal, leading to

$$\text{Speedup} = \frac{\text{CPI uniplined}}{1 + \text{Pipeline stall cycles per instruction}}$$

One important simple case is where all instructions take the same number of cycles, which must also equal the number of pipeline stages (also called the *depth of the pipeline*). In this case, the uniplined CPI is equal to the depth of the pipeline, leading to

$$\text{Speedup} = \frac{\text{Pipeline depth}}{1 + \text{Pipeline stall cycles per instruction}}$$

If there are no pipeline stalls, this leads to the intuitive result that pipelining can improve performance by the depth of the pipeline.

## Data Hazards

A major effect of pipelining is to change the relative timing of instructions by overlapping their execution. This overlap introduces data and control hazards. Data hazards occur when the pipeline changes the order of read/write accesses to operands so that the order differs from the order seen by sequentially executing instructions on an uniplined processor. Assume instruction  $i$  occurs in program order before instruction  $j$  and both instructions use register  $x$ , then there are three different types of hazards that can occur between  $i$  and  $j$ :

1. Read After Write (RAW) hazard: the most common, these occur when a read of register  $x$  by instruction  $j$  occurs before the write of register  $x$  by instruction  $i$ . If this hazard were not prevented instruction  $j$  would use the wrong value of  $x$ .
2. Write After Read (WAR) hazard: this hazard occurs when read of register  $x$  by instruction  $i$  occurs after a write of register  $x$  by instruction  $j$ . In this case, instruction  $i$  would use the wrong value of  $x$ . WAR hazards are impossible in the simple five stage, integer pipeline, but they occur when instructions are reordered, as we will see when we discuss dynamically scheduled pipelines beginning on page C.65.
3. Write After Write (WAW) hazard: this hazard occurs when write of register  $x$  by instruction  $i$  occurs after a write of register  $x$  by instruction  $j$ . When this occurs, register  $x$  will have the wrong value going forward. WAR hazards are also impossible in the simple five stage, integer pipeline, but they occur when instructions are reordered or when running times vary, as we will see later.

Chapter 3 explores the issues of data dependence and hazards in much more detail. For now, we focus only on RAW hazards.

Consider the pipelined execution of these instructions:

```
add x1,x2,x3
sub x4,x1,x5
and x6,x1,x7
or x8,x1,x9
xor x10,x1,x11
```

All the instructions after the `add` use the result of the `add` instruction. As shown in [Figure C.4](#), the `add` instruction writes the value of `x1` in the WB pipe stage, but the `sub` instruction reads the value during its ID stage, which results in a RAW hazard. Unless precautions are taken to prevent it, the `sub` instruction will read the wrong value and try to use it. In fact, the value used by the `sub` instruction is not even deterministic: though we might think it logical to assume that `sub` would always use the value of `x1` that was assigned by an instruction prior to `add`, this is not

**Figure C.4** The use of the result of the `add` instruction in the next three instructions causes a hazard, because the register is not written until after those instructions read it.

always the case. If an interrupt should occur between the `add` and `sub` instructions, the WB stage of the `add` will complete, and the value of `x1` at that point will be the result of the `add`. This unpredictable behavior is obviously unacceptable.

The `and` instruction also creates a possible RAW hazard. As we can see from [Figure C.4](#), the write of `x1` does not complete until the end of clock cycle 5. Thus, the `and` instruction that reads the registers during clock cycle 4 will receive the wrong results.

The `xor` instruction operates properly because its register read occurs in clock cycle 6, after the register write. The `or` instruction also operates without incurring a hazard because we perform the register file reads in the second half of the cycle and the writes in the first half. Note that the `xor` instruction still depends on the `add`, but it no longer creates a hazard; a topic we explore in more detail in [Chapter 3](#).

The next subsection discusses a technique to eliminate the stalls for the hazard involving the `sub` and `and` instructions.

### *Minimizing Data Hazard Stalls by Forwarding*

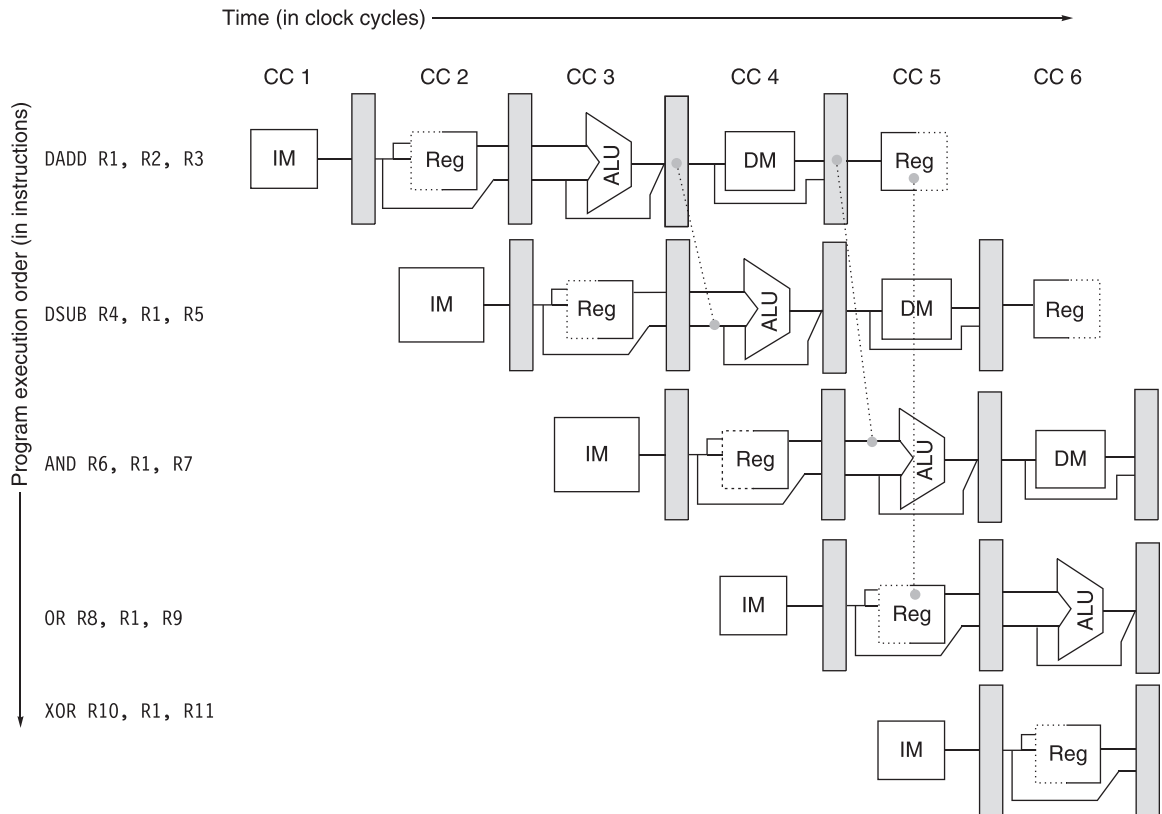

The problem posed in [Figure C.4](#) can be solved with a simple hardware technique called *forwarding* (also called *bypassing* and sometimes *short-circuiting*). The key insight in forwarding is that the result is not really needed by the `sub` until after the `add` actually produces it. If the result can be moved from the pipeline register where the `add` stores it to where the `sub` needs it, then the need for a stall can be avoided. Using this observation, forwarding works as follows:

1. The ALU result from both the EX/MEM and MEM/WB pipeline registers is always fed back to the ALU inputs.
2. If the forwarding hardware detects that the previous ALU operation has written the register corresponding to a source for the current ALU operation, control logic selects the forwarded result as the ALU input rather than the value read from the register file.

Notice that with forwarding, if the `sub` is stalled, the `add` will be completed and the bypass will not be activated. This relationship is also true for the case of an interrupt between the two instructions.

As the example in [Figure C.4](#) shows, we need to forward results not only from the immediately previous instruction but also possibly from an instruction that started two cycles earlier. [Figure C.5](#) shows our example with the bypass paths in place and highlighting the timing of the register read and writes. This code sequence can be executed without stalls.

Forwarding can be generalized to include passing a result directly to the functional unit that requires it: a result is forwarded from the pipeline register corresponding to the output of one unit to the input of another, rather than just from

**Figure C.5** A set of instructions that depends on the add result uses forwarding paths to avoid the data hazard. The inputs for the `sub` and `and` instructions forward from the pipeline registers to the first ALU input. The `or` receives its result by forwarding through the register file, which is easily accomplished by reading the registers in the second half of the cycle and writing in the first half, as the dashed lines on the registers indicate. Notice that the forwarded result can go to either ALU input; in fact, both ALU inputs could use forwarded inputs from either the same pipeline register or from different pipeline registers. This would occur, for example, if the `and` instruction was `and x6, x1, x4`.

the result of a unit to the input of the same unit. Take, for example, the following sequence:

```
add x1, x2, x3
ld x4, 0(x1)
sd x4, 12(x1)
```

To prevent a stall in this sequence, we would need to forward the values of the ALU output and memory unit output from the pipeline registers to the ALU and data memory inputs. [Figure C.6](#) shows all the forwarding paths for this example.

**Figure C.6 Forwarding of operand required by stores during MEM.** The result of the load is forwarded from the memory output to the memory input to be stored. In addition, the ALU output is forwarded to the ALU input for the address calculation of both the load and the store (this is no different than forwarding to another ALU operation). If the store depended on an immediately preceding ALU operation (not shown herein), the result would need to be forwarded to prevent a stall.

### *Data Hazards Requiring Stalls*

Unfortunately, not all potential data hazards can be handled by bypassing. Consider the following sequence of instructions:

```
ld x1,0(x2)
sub x4,x1,x5
and x6,x1,x7
or x8,x1,x9
```

The pipelined data path with the bypass paths for this example is shown in [Figure C.7](#). This case is different from the situation with back-to-back ALU operations. The `ld` instruction does not have the data until the end of clock cycle 4 (its MEM cycle), while the `sub` instruction needs to have the data by the beginning of that clock cycle. Thus, the data hazard from using the result of a load instruction cannot be completely eliminated with simple hardware. As [Figure C.7](#) shows, such a forwarding path would have to operate backward in time—a capability not yet available to computer designers! We *can* forward the result immediately to the ALU from the pipeline registers for use in the `and` operation, which begins 2 clock cycles after the load. Likewise, the `or` instruction has no problem, because it receives the value through the register file. For the `sub` instruction, the forwarded

**Figure C.7** The load instruction can bypass its results to the and and or instructions, but not to the sub, because that would mean forwarding the result in “negative time.”

result arrives too late—at the end of a clock cycle, when it is needed at the beginning.

The load instruction has a delay or latency that cannot be eliminated by forwarding alone. Instead, we need to add hardware, called a *pipeline interlock*, to preserve the correct execution pattern. In general, a pipeline interlock detects a hazard and stalls the pipeline until the hazard is cleared. In this case, the interlock stalls the pipeline, beginning with the instruction that wants to use the data until the source instruction produces it. This pipeline interlock introduces a stall or bubble, just as it did for the structural hazard. The CPI for the stalled instruction increases by the length of the stall (1 clock cycle in this case).

Figure C.8 shows the pipeline before and after the stall using the names of the pipeline stages. Because the stall causes the instructions starting with the `sub` to move one cycle later in time, the forwarding to the `and` instruction now goes through the register file, and no forwarding at all is needed for the `or` instruction. The insertion of the bubble causes the number of cycles to complete this sequence to grow by one. No instruction is started during clock cycle 4 (and none finishes during cycle 6).

|              |    |    |    |       |     |     |     |        |
|--------------|----|----|----|-------|-----|-----|-----|--------|
| ld x1,0(x2)  | IF | ID | EX | MEM   | WB  |     |     |        |
| sub x4,x1,x5 |    | IF | ID | EX    | MEM | WB  |     |        |
| and x6,x1,x7 |    |    | IF | ID    | EX  | MEM | WB  |        |
| or x8,x1,x9  |    |    |    | IF    | ID  | EX  | MEM | WB     |
| ld x1,0(x2)  | IF | ID | EX | MEM   | WB  |     |     |        |
| sub x4,x1,x5 |    | IF | ID | Stall | EX  | MEM | WB  |        |
| and x6,x1,x7 |    |    | IF | Stall | ID  | EX  | MEM | WB     |
| or x8,x1,x9  |    |    |    | Stall | IF  | ID  | EX  | MEM WB |

**Figure C.8** In the top half, we can see why a stall is needed: the MEM cycle of the load produces a value that is needed in the EX cycle of the sub, which occurs at the same time. This problem is solved by inserting a stall, as shown in the bottom half.

## Branch Hazards

*Control hazards* can cause a greater performance loss for our RISC V pipeline than do data hazards. When a branch is executed, it may or may not change the PC to something other than its current value plus 4. Recall that if a branch changes the PC to its target address, it is a *taken* branch; if it falls through, it is *not taken*, or *untaken*. If instruction *i* is a taken branch, then the PC is usually not changed until the end of ID, after the completion of the address calculation and comparison.

Figure C.9 shows that the simplest method of dealing with branches is to redo the fetch of the instruction following a branch, once we detect the branch during ID (when instructions are decoded). The first IF cycle is essentially a stall, because it never performs useful work. You may have noticed that if the branch is untaken, then the repetition of the IF stage is unnecessary because the correct instruction was indeed fetched. We will develop several schemes to take advantage of this fact shortly.

One stall cycle for every branch will yield a performance loss of 10% to 30% depending on the branch frequency, so we will examine some techniques to deal with this loss.

|                      |    |    |    |     |    |     |     |
|----------------------|----|----|----|-----|----|-----|-----|
| Branch instruction   | IF | ID | EX | MEM | WB |     |     |
| Branch successor     |    | IF | IF | ID  | EX | MEM | WB  |
| Branch successor + 1 |    |    |    | IF  | ID | EX  | MEM |
| Branch successor + 2 |    |    |    |     | IF | ID  | EX  |

**Figure C.9** A branch causes a one-cycle stall in the five-stage pipeline. The instruction after the branch is fetched, but the instruction is ignored, and the fetch is restarted once the branch target is known. It is probably obvious that if the branch is not taken, the second IF for branch successor is redundant. This will be addressed shortly.

### Reducing Pipeline Branch Penalties

There are many methods for dealing with the pipeline stalls caused by branch delay; we discuss four simple compile time schemes in this subsection. In these four schemes the actions for a branch are static—they are fixed for each branch during the entire execution. The software can try to minimize the branch penalty using knowledge of the hardware scheme and of branch behavior. We will then look at hardware-based schemes that dynamically predict branch behavior, and [Chapter 3](#) looks at more powerful hardware techniques for dynamic branch prediction.

The simplest scheme to handle branches is to *freeze* or *flush* the pipeline, holding or deleting any instructions after the branch until the branch destination is known. The attractiveness of this solution lies primarily in its simplicity both for hardware and software. It is the solution used earlier in the pipeline shown in [Figure C.9](#). In this case, the branch penalty is fixed and cannot be reduced by software.

A higher-performance, and only slightly more complex, scheme is to treat every branch as not taken, simply allowing the hardware to continue as if the branch were not executed. Here, care must be taken not to change the processor state until the branch outcome is definitely known. The complexity of this scheme arises from having to know when the state might be changed by an instruction and how to “back out” such a change.

In the simple five-stage pipeline, this *predicted-not-taken* or *predicted-untaken* scheme is implemented by continuing to fetch instructions as if the branch were a normal instruction. The pipeline looks as if nothing out of the ordinary is happening. If the branch is taken, however, we need to turn the fetched instruction into a no-op and restart the fetch at the target address. [Figure C.10](#) shows both situations.

An alternative scheme is to treat every branch as taken. As soon as the branch is decoded and the target address is computed, we assume the branch to be taken and

|                            |    |    |      |      |      |      |     |     |    |
|----------------------------|----|----|------|------|------|------|-----|-----|----|
| Untaken branch instruction | IF | ID | EX   | MEM  | WB   |      |     |     |    |
| Instruction $i + 1$        |    | IF | ID   | EX   | MEM  | WB   |     |     |    |
| Instruction $i + 2$        |    |    | IF   | ID   | EX   | MEM  | WB  |     |    |
| Instruction $i + 3$        |    |    |      | IF   | ID   | EX   | MEM | WB  |    |
| Instruction $i + 4$        |    |    |      |      | IF   | ID   | EX  | MEM | WB |
|                            |    |    |      |      |      |      |     |     |    |
| Taken branch instruction   | IF | ID | EX   | MEM  | WB   |      |     |     |    |
| Instruction $i + 1$        |    | IF | idle | idle | idle | idle |     |     |    |
| Branch target              |    |    | IF   | ID   | EX   | MEM  | WB  |     |    |
| Branch target + 1          |    |    |      | IF   | ID   | EX   | MEM | WB  |    |
| Branch target + 2          |    |    |      |      | IF   | ID   | EX  | MEM | WB |

**Figure C.10** The predicted-not-taken scheme and the pipeline sequence when the branch is untaken (top) and taken (bottom). When the branch is untaken, determined during ID, we fetch the fall-through and just continue. If the branch is taken during ID, we restart the fetch at the branch target. This causes all instructions following the branch to stall 1 clock cycle.

begin fetching and executing at the target. This buys us a one-cycle improvement when the branch is actually taken, because we know the target address at the end of ID, one cycle before we know whether the branch condition is satisfied in the ALU stage. In either a predicted-taken or predicted-not-taken scheme, the compiler can improve performance by organizing the code so that the most frequent path matches the hardware's choice.

A fourth scheme, which was heavily used in early RISC processors is called *delayed branch*. In a delayed branch, the execution cycle with a branch delay of one is

```
branch instruction
sequential successor1
branch target if taken
```

The sequential successor is in the *branch delay slot*. This instruction is executed whether or not the branch is taken. The pipeline behavior of the five-stage pipeline with a branch delay is shown in Figure C.11. Although it is possible to have a branch delay longer than one, in practice almost all processors with delayed branch have a single instruction delay; other techniques are used if the pipeline has a longer potential branch penalty. The job of the compiler is to make the successor instructions valid and useful.

Although the delayed branch was useful for short simple pipelines at a time when hardware prediction was too expensive, the technique complicates implementation when there is dynamic branch prediction. For this reason, RISC V appropriately omitted delayed branches.

|                                    |    |    |    |     |     |     |     |     |    |
|------------------------------------|----|----|----|-----|-----|-----|-----|-----|----|
| Untaken branch instruction         | IF | ID | EX | MEM | WB  |     |     |     |    |
| Branch delay instruction ( $i+1$ ) |    | IF | ID | EX  | MEM | WB  |     |     |    |
| Instruction $i+2$                  |    |    | IF | ID  | EX  | MEM | WB  |     |    |
| Instruction $i+3$                  |    |    |    | IF  | ID  | EX  | MEM | WB  |    |
| Instruction $i+4$                  |    |    |    |     | IF  | ID  | EX  | MEM | WB |
|                                    |    |    |    |     |     |     |     |     |    |
| Taken branch instruction           | IF | ID | EX | MEM | WB  |     |     |     |    |
| Branch delay instruction ( $i+1$ ) |    | IF | ID | EX  | MEM | WB  |     |     |    |
| Branch target                      |    |    | IF | ID  | EX  | MEM | WB  |     |    |
| Branch target+1                    |    |    |    | IF  | ID  | EX  | MEM | WB  |    |
| Branch target+2                    |    |    |    |     | IF  | ID  | EX  | MEM | WB |

**Figure C.11** The behavior of a delayed branch is the same whether or not the branch is taken. The instructions in the delay slot (there was only one delay slot for most RISC architectures that incorporated them) are executed. If the branch is untaken, execution continues with the instruction after the branch delay instruction; if the branch is taken, execution continues at the branch target. When the instruction in the branch delay slot is also a branch, the meaning is unclear: if the branch is not taken, what should happen to the branch in the branch delay slot? Because of this confusion, architectures with delay branches often disallow putting a branch in the delay slot.

### Performance of Branch Schemes

What is the effective performance of each of these schemes? The effective pipeline speedup with branch penalties, assuming an ideal CPI of 1, is

$$\text{Pipeline speedup} = \frac{\text{Pipeline depth}}{1 + \text{Pipeline stall cycles from branches}}$$

Because of the following:

$$\text{Pipeline stall cycles from branches} = \text{Branch frequency} \times \text{Branch penalty}$$

we obtain:

$$\text{Pipeline speedup} = \frac{\text{Pipeline depth}}{1 + \text{Branch frequency} \times \text{Branch penalty}}$$

The branch frequency and branch penalty can have a component from both unconditional and conditional branches. However, the latter dominate because they are more frequent.

---

**Example** For a deeper pipeline, such as that in a MIPS R4000 and later RISC processors, it takes at least three pipeline stages before the branch-target address is known and an additional cycle before the branch condition is evaluated, assuming no stalls on the registers in the conditional comparison. A three-stage delay leads to the branch penalties for the three simplest prediction schemes listed in [Figure C.12](#).

Find the effective addition to the CPI arising from branches for this pipeline, assuming the following frequencies:

|                             |     |
|-----------------------------|-----|
| Unconditional branch        | 4%  |
| Conditional branch, untaken | 6%  |
| Conditional branch, taken   | 10% |

**Answer** We find the CPIs by multiplying the relative frequency of unconditional, conditional untaken, and conditional taken branches by the respective penalties. The results are shown in [Figure C.13](#).

| Branch scheme     | Penalty unconditional | Penalty untaken | Penalty taken |
|-------------------|-----------------------|-----------------|---------------|
| Flush pipeline    | 2                     | 3               | 3             |
| Predicted taken   | 2                     | 3               | 2             |
| Predicted untaken | 2                     | 0               | 3             |

**Figure C.12** Branch penalties for the three simplest prediction schemes for a deeper pipeline.

| Branch scheme      | Additions to the CPI from branch costs |                              |                            |              |
|--------------------|----------------------------------------|------------------------------|----------------------------|--------------|
|                    | Unconditional branches                 | Untaken conditional branches | Taken conditional branches | All branches |
| Frequency of event | 4%                                     | 6%                           | 10%                        | 20%          |
| Stall pipeline     | 0.08                                   | 0.18                         | 0.30                       | 0.56         |

| Predicted untaken  | 0.08                                   | 0.00                         | 0.30                       | 0.38         |

**Figure C.13** CPI penalties for three branch-prediction schemes and a deeper pipeline.

The differences among the schemes are substantially increased with this longer delay. If the base CPI were 1 and branches were the only source of stalls, the ideal pipeline would be 1.56 times faster than a pipeline that used the stall-pipeline scheme. The predicted-untaken scheme would be 1.13 times better than the stall-pipeline scheme under the same assumptions.

### Reducing the Cost of Branches Through Prediction

As pipelines get deeper and the potential penalty of branches increases, using delayed branches and similar schemes becomes insufficient. Instead, we need to turn to more aggressive means for predicting branches. Such schemes fall into two classes: low-cost static schemes that rely on information available at compile time and strategies that predict branches dynamically based on program behavior. We discuss both approaches here.

#### Static Branch Prediction

A key way to improve compile-time branch prediction is to use profile information collected from earlier runs. The key observation that makes this worthwhile is that the behavior of branches is often bimodally distributed; that is, an individual branch is often highly biased toward taken or untaken. [Figure C.14](#) shows the success of branch prediction using this strategy. The same input data were used for runs and for collecting the profile; other studies have shown that changing the input so that the profile is for a different run leads to only a small change in the accuracy of profile-based prediction.

The effectiveness of any branch prediction scheme depends both on the accuracy of the scheme and the frequency of conditional branches, which vary in SPEC from 3% to 24%. The fact that the misprediction rate for the integer programs is higher and such programs typically have a higher branch frequency is a major limitation for static branch prediction. In the next section, we consider dynamic branch predictors, which most recent processors have employed.

**Figure C.14** Misprediction rate on SPEC92 for a profile-based predictor varies widely but is generally better for the floating-point programs, which have an average misprediction rate of 9% with a standard deviation of 4%, than for the integer programs, which have an average misprediction rate of 15% with a standard deviation of 5%. The actual performance depends on both the prediction accuracy and the branch frequency, which vary from 3% to 24%.

## Dynamic Branch Prediction and Branch-Prediction Buffers

The simplest dynamic branch-prediction scheme is a *branch-prediction buffer* or *branch history table*. A branch-prediction buffer is a small memory indexed by the lower portion of the address of the branch instruction. The memory contains a bit that says whether the branch was recently taken or not. This scheme is the simplest sort of buffer; it has no tags and is useful only to reduce the branch delay when it is longer than the time to compute the possible target PCs.

With such a buffer, we don't know, in fact, if the prediction is correct—it may have been put there by another branch that has the same low-order address bits. But this doesn't matter. The prediction is a hint that is assumed to be correct, and fetching begins in the predicted direction. If the hint turns out to be wrong, the prediction bit is inverted and stored back.

This buffer is effectively a cache where every access is a hit, and, as we will see, the performance of the buffer depends on both how often the prediction is for the branch of interest and how accurate the prediction is when it matches. Before we analyze the performance, it is useful to make a small, but important, improvement in the accuracy of the branch-prediction scheme.

This simple 1-bit prediction scheme has a performance shortcoming: even if a branch is almost always taken, we will likely predict incorrectly twice, rather than once, when it is not taken, because the misprediction causes the prediction bit to be flipped.

To remedy this weakness, 2-bit prediction schemes are often used. In a 2-bit scheme, a prediction must miss twice before it is changed. [Figure C.15](#) shows the finite-state processor for a 2-bit prediction scheme.

A branch-prediction buffer can be implemented as a small, special “cache” accessed with the instruction address during the IF pipe stage, or as a pair of bits attached to each block in the instruction cache and fetched with the instruction. If the instruction is decoded as a branch and if the branch is predicted as taken, fetching begins from the target as soon as the PC is known. Otherwise, sequential fetching and executing continue. As [Figure C.15](#) shows, if the prediction turns out to be wrong, the prediction bits are changed.

What kind of accuracy can be expected from a branch-prediction buffer using 2 bits per entry on real applications? [Figure C.16](#) shows that for the SPEC89 benchmarks a branch-prediction buffer with 4096 entries results in a prediction accuracy

**Figure C.15** The states in a 2-bit prediction scheme. By using 2 bits rather than 1, a branch that strongly favors taken or not taken—as many branches do—will be mispredicted less often than with a 1-bit predictor. The 2 bits are used to encode the four states in the system. The 2-bit scheme is actually a specialization of a more general scheme that has an  $n$ -bit saturating counter for each entry in the prediction buffer. With an  $n$ -bit counter, the counter can take on values between 0 and  $2^n - 1$ : when the counter is greater than or equal to one-half of its maximum value ( $2^{n-1}$ ), the branch is predicted as taken; otherwise, it is predicted as untaken. Studies of  $n$ -bit predictors have shown that the 2-bit predictors do almost as well, thus most systems rely on 2-bit branch predictors rather than the more general  $n$ -bit predictors.

**Figure C.16 Prediction accuracy of a 4096-entry 2-bit prediction buffer for the SPEC89 benchmarks.** The misprediction rate for the integer benchmarks (gcc, espresso, eqntott, and li) is substantially higher (average of 11%) than that for the floating-point programs (average of 4%). Omitting the floating-point kernels (nasa7, matrix300, and tomcatv) still yields a higher accuracy for the FP benchmarks than for the integer benchmarks. These data, as well as the rest of the data in this section, are taken from a branch-prediction study done using the IBM Power architecture and optimized code for that system. See [Pan et al. \(1992\)](#). Although these data are for an older version of a subset of the SPEC benchmarks, the newer benchmarks are larger and would show slightly worse behavior, especially for the integer benchmarks.

ranging from over 99% to 82%, or a *misprediction rate* of 1%–18%. A 4K entry buffer, like that used for these results, is considered small in 2017, and a larger buffer could produce somewhat better results.

As we try to exploit more ILP, the accuracy of our branch prediction becomes critical. As we can see in [Figure C.16](#), the accuracy of the predictors for integer programs, which typically also have higher branch frequencies, is lower than for the loop-intensive scientific programs. We can attack this problem in two ways: by increasing the size of the buffer and by increasing the accuracy of the scheme we use for each prediction. A buffer with 4K entries, however, as [Figure C.17](#) shows, performs quite comparably to an infinite buffer, at least for benchmarks like those in SPEC. The data in [Figure C.17](#) make it clear that the hit rate of the buffer is not the major limiting factor. As we mentioned, simply increasing the number of bits per predictor without changing the predictor structure also has little impact. Instead, we need to look at how we might increase the accuracy of each predictor, as we will in [Chapter 3](#).

**Figure C.17** Prediction accuracy of a 4096-entry 2-bit prediction buffer versus an infinite buffer for the SPEC89 benchmarks. Although these data are for an older version of a subset of the SPEC benchmarks, the results would be comparable for newer versions with perhaps as many as 8K entries needed to match an infinite 2-bit predictor.

## C.3

### How Is Pipelining Implemented?

Before we proceed to basic pipelining, we need to review a simple implementation of an unpipelined version of RISC V.

#### A Simple Implementation of RISC V

In this section we follow the style of [Section C.1](#), showing first a simple unpipe-lined implementation and then the pipelined implementation. This time, however, our example is specific to the RISC V architecture.

In this subsection, we focus on a pipeline for an integer subset of RISC V that consists of load-store word, branch equal, and integer ALU operations. Later in this appendix we will incorporate the basic floating-point operations. Although we discuss only a subset of RISC V, the basic principles can be extended to handle all the instructions; for example, adding store involves some additional computing of the immediate field. We initially used a less aggressive implementation of a branch instruction. We show how to implement the more aggressive version at the end of this section.

Every RISC V instruction can be implemented in, at most, 5 clock cycles. The 5 clock cycles are as follows:

1. *Instruction fetch cycle (IF):*

$$\begin{aligned} \text{IR} &\leftarrow \text{Mem}[\text{PC}]; \\ \text{NPC} &\leftarrow \text{PC} + 4; \end{aligned}$$

*Operation*—Send out the PC and fetch the instruction from memory into the instruction register (IR); increment the PC by 4 to address the next sequential instruction. The IR is used to hold the instruction that will be needed on subsequent clock cycles; likewise, the register NPC is used to hold the next sequential PC.

2. *Instruction decode/register fetch cycle (ID):*

$$\begin{aligned} \text{A} &\leftarrow \text{Regs}[\text{rs1}]; \\ \text{B} &\leftarrow \text{Regs}[\text{rs2}]; \\ \text{Imm} &\leftarrow \text{sign-extended immediate field of IR}; \end{aligned}$$

*Operation*—Decode the instruction and access the register file to read the registers (rs1 and rs2 are the register specifiers). The outputs of the general-purpose registers are read into two temporary registers (A and B) for use in later clock cycles. The lower 16 bits of the IR are also sign extended and stored into the temporary register Imm, for use in the next cycle.

Decoding is done in parallel with reading registers, which is possible because these fields are at a fixed location in the RISC V instruction format. Because the immediate portion of a load and an ALU immediate is located in an identical place in every RISC V instruction, the sign-extended immediate is also calculated during this cycle in case it is needed in the next cycle. For stores, a separate sign-extension is needed, because the immediate field is split in two pieces.

3. *Execution/effective address cycle (EX):*

The ALU operates on the operands prepared in the prior cycle, performing one of four functions depending on the RISC V instruction type:

■ Memory reference:

$$\text{ALUOutput} \leftarrow \text{A} + \text{Imm};$$

*Operation*—The ALU adds the operands to form the effective address and places the result into the register ALUOutput.

- Register-register ALU instruction:

$$\text{ALUOutput} \leftarrow A \text{ func } B;$$

*Operation*—The ALU performs the operation specified by the function code (a combination of the func3 and func7 fields) on the value in register A and on the value in register B. The result is placed in the temporary register ALUOutput.

- Register-Immediate ALU instruction:

$$\text{ALUOutput} \leftarrow A \text{ op } \text{Imm};$$

*Operation*—The ALU performs the operation specified by the opcode on the value in register A and on the value in register Imm. The result is placed in the temporary register ALUOutput.

- Branch:

$$\begin{aligned} \text{ALUOutput} &\leftarrow \text{NPC} + (\text{Imm} \ll 2); \\ \text{Cond} &\leftarrow (A == B) \end{aligned}$$

*Operation*—The ALU adds the NPC to the sign-extended immediate value in Imm, which is shifted left by 2 bits to create a word offset, to compute the address of the branch target. Register A, which has been read in the prior cycle, is checked to determine whether the branch is taken, by comparison with Register B, because we consider only branch equal.

The load-store architecture of RISC V means that effective address and execution cycles can be combined into a single clock cycle, because no instruction needs to simultaneously calculate a data address, calculate an instruction target address, and perform an operation on the data. The other integer instructions not included herein are jumps of various forms, which are similar to branches.

#### 4. *Memory access/branch completion cycle (MEM):*

The PC is updated for all instructions:  $\text{PC} \leftarrow \text{NPC};$

- Memory reference:

$$\begin{aligned} \text{LMD} &\leftarrow \text{Mem}[\text{ALUOutput}] \text{ or} \\ \text{Mem}[\text{ALUOutput}] &\leftarrow B; \end{aligned}$$

*Operation*—Access memory if needed. If the instruction is a load, data return from memory and are placed in the LMD (load memory data) register; if it is a store, then the data from the B register are written into memory. In either case, the address used is the one computed during the prior cycle and stored in the register ALUOutput.

- Branch:

$\text{if (cond) PC} \leftarrow \text{ALUOutput}$

*Operation*—If the instruction branches, the PC is replaced with the branch destination address in the register ALUOutput.

5. *Write-back cycle (WB):*

- Register-register or Register-immediate ALU instruction:

$\text{Regs[rd]} \leftarrow \text{ALUOutput};$

- Load instruction:

$\text{Regs[rd]} \leftarrow \text{LMD};$

*Operation*—Write the result into the register file, whether it comes from the memory system (which is in LMD) or from the ALU (which is in ALUOutput) with rd designating the register.

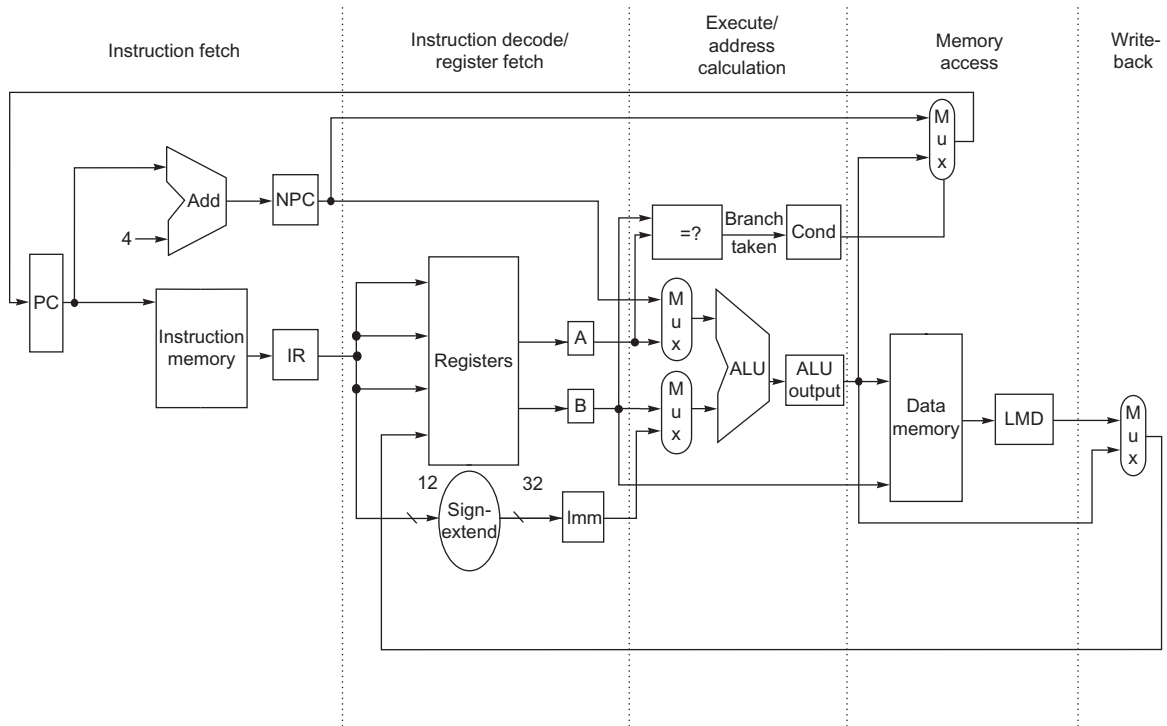

Figure C.18 shows how an instruction flows through the data path. At the end of each clock cycle, every value computed during that clock cycle and required on a later clock cycle (whether for this instruction or the next) is written into a storage device, which may be memory, a general-purpose register, the PC, or a temporary register (i.e., LMD, Imm, A, B, IR, NPC, ALUOutput, or Cond). The temporary registers hold values between clock cycles for one instruction, while the other storage elements are visible parts of the state and hold values between successive instructions.

Although all processors today are pipelined, this multicycle implementation is a reasonable approximation of how most processors would have been implemented in earlier times. A simple finite-state machine could be used to implement the control following the five-cycle structure shown herein. For a much more complex processor, microcode control could be used. In either event, an instruction sequence like the one described in this section would determine the structure of the control.

There are some hardware redundancies that could be eliminated in this multicycle implementation. For example, there are two ALUs: one to increment the PC and one used for effective address and ALU computation. Because they are not needed on the same clock cycle, we could merge them by adding additional multiplexers and sharing the same ALU. Likewise, instructions and data could be stored in the same memory, because the data and instruction accesses happen on different clock cycles.

Rather than optimize this simple implementation, we will leave the design as it is in Figure C.18, because this provides us with a better base for the pipelined implementation.

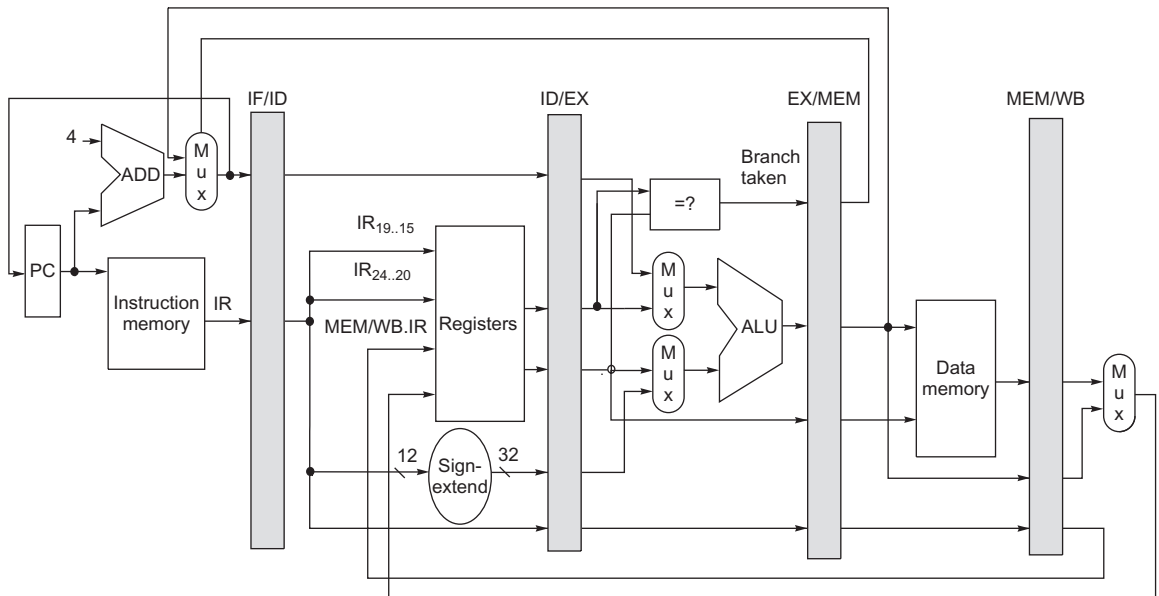

**Figure C.18** The implementation of the RISC V data path allows every instruction to be executed in 4 or 5 clock cycles. Although the PC is shown in the portion of the data path that is used in instruction fetch and the registers are shown in the portion of the data path that is used in instruction decode/register fetch, both of these functional units are read as well as written by an instruction. Although we show these functional units in the cycle corresponding to where they are read, the PC is written during the memory access clock cycle and the registers are written during the write-back clock cycle. In both cases, the writes in later pipe stages are indicated by the multiplexer output (in memory access or write-back), which carries a value back to the PC or registers. These backward-flowing signals introduce much of the complexity of pipelining, because they indicate the possibility of hazards.

## A Basic Pipeline for RISC V

As before, we can pipeline the data path of [Figure C.18](#) with almost no changes by starting a new instruction on each clock cycle. Because every pipe stage is active on every clock cycle, all operations in a pipe stage must complete in 1 clock cycle and any combination of operations must be able to occur at once. Furthermore, pipelining the data path requires that values passed from one pipe stage to the next must be placed in registers. [Figure C.19](#) shows the RISC V pipeline with the appropriate registers, called *pipeline registers* or *pipeline latches*, between each pipeline stage. The registers are labeled with the names of the stages they connect.

**Figure C.19** The data path is pipelined by adding a set of registers, one between each pair of pipe stages. The registers serve to convey values and control information from one stage to the next. We can also think of the PC as a pipeline register, which sits before the IF stage of the pipeline, leading to one pipeline register for each pipe stage. Recall that the PC is an edge-triggered register written at the end of the clock cycle; hence, there is no race condition in writing the PC. The selection multiplexer for the PC has been moved so that the PC is written in exactly one stage (IF). If we didn't move it, there would be a conflict when a branch occurred, because two instructions would try to write different values into the PC. Most of the data paths flow from left to right, which is from earlier in time to later. The paths flowing from right to left (which carry the register write-back information and PC information on a branch) introduce complications into our pipeline.

Figure C.19 is drawn so that connections through the pipeline registers from one stage to another are clear.

All of the registers needed to hold values temporarily between clock cycles within one instruction are subsumed into these pipeline registers. The fields of the instruction register (IR), which is part of the IF/ID register, are labeled when they are used to supply register names. The pipeline registers carry both data and control from one pipeline stage to the next. Any value needed on a later pipeline stage must be placed in such a register and copied from one pipeline register to the next, until it is no longer needed. If we tried to just use the temporary registers we had in our earlier unpipelined data path, values could be overwritten before all uses were completed. For example, the field of a register operand used for a write on a load or ALU operation is supplied from the MEM/WB pipeline register rather than from the IF/ID register. This is because we want a load or ALU operation to write the register designated by that operation, not the register field of the

instruction currently transitioning from IF to ID! This destination register field is simply copied from one pipeline register to the next, until it is needed during the WB stage.

Any instruction is active in exactly one stage of the pipeline at a time; therefore, any actions taken on behalf of an instruction occur between a pair of pipeline registers. Thus, we can also look at the activities of the pipeline by examining what has to happen on any pipeline stage depending on the instruction type. [Figure C.20](#) shows this view. Fields of the pipeline registers are named so as to show the flow

| Stage | Any instruction                                                                                                                                                     |                                                                                                                |                                                                                                     |
|-------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------|
| IF    | IF/ID.IR ← Mem[PC]<br>IF/ID.NPC, PC ← (if ((EX/MEM.opcode == branch) & EX/MEM.cond){EX/MEM.ALUOutput} else {PC+4});                                                 |                                                                                                                |                                                                                                     |
| ID    | ID/EX.A ← Regs[IF/ID.IR[rs1]]; ID/EX.B ← Regs[IF/ID.IR[rs2]];<br>ID/EX.NPC ← IF/ID.NPC; ID/EX.IR ← IF/ID.IR;<br>ID/EX.Imm ← sign-extend(IF/ID.IR[immediate field]); |                                                                                                                |                                                                                                     |
|       | ALU instruction                                                                                                                                                     | Load instruction                                                                                               | Branch instruction                                                                                  |

| WB    | Regs[MEM/WB.IR[rd]] ←<br>MEM/WB.ALUOutput;                                                                                                                          | For load only:<br>Regs[MEM/WB.IR[rd]] ←<br>MEM/WB.LMD;                                                         |                                                                                                     |

**Figure C.20 Events on every pipe stage of the RISC V pipeline.** Let's review the actions in the stages that are specific to the pipeline organization. In IF, in addition to fetching the instruction and computing the new PC, we store the incremented PC both into the PC and into a pipeline register (NPC) for later use in computing the branch-target address. This structure is the same as the organization in [Figure C.19](#), where the PC is updated in IF from one of two sources. In ID, we fetch the registers, extend the sign of the 12 bits of the IR (the immediate field), and pass along the IR and NPC. During EX, we perform an ALU operation or an address calculation; we pass along the IR and the B register (if the instruction is a store). We also set the value of cond to 1 if the instruction is a taken branch. During the MEM phase, we cycle the memory, write the PC if needed, and pass along values needed in the final pipe stage. Finally, during WB, we update the register field from either the ALU output or the loaded value. For simplicity we always pass the entire IR from one stage to the next, although as an instruction proceeds down the pipeline, less and less of the IR is needed.

of data from one stage to the next. Notice that the actions in the first two stages are independent of the current instruction type; they must be independent because the instruction is not decoded until the end of the ID stage. The IF activity depends on whether the instruction in EX/MEM is a taken branch. If so, then the branch-target address of the branch instruction in EX/MEM is written into the PC at the end of IF; otherwise, the incremented PC will be written back. (As we said earlier, this effect of branches leads to complications in the pipeline that we deal with in the next few sections.) The fixed-position encoding of the register source operands is critical to allowing the registers to be fetched during ID.

To control this simple pipeline we need only determine how to set the control for the four multiplexers in the data path of [Figure C.19](#). The two multiplexers in the ALU stage are set depending on the instruction type, which is dictated by the IR field of the ID/EX register. The top ALU input multiplexer is set by whether the instruction is a branch or not, and the bottom multiplexer is set by whether the instruction is a register-register ALU operation or any other type of operation. The multiplexer in the IF stage chooses whether to use the value of the incremented PC or the value of the EX/MEM.ALUOutput (the branch target) to write into the PC. This multiplexer is controlled by the field EX/MEM.cond. The fourth multiplexer is controlled by whether the instruction in the WB stage is a load or an ALU operation. In addition to these four multiplexers, there is one additional multiplexer needed that is not drawn in [Figure C.19](#), but whose existence is clear from looking at the WB stage of an ALU operation. The destination register field is in one of two different places depending on the instruction type (register-register ALU versus either ALU immediate or load). Thus, we will need a multiplexer to choose the correct portion of the IR in the MEM/WB register to specify the register destination field, assuming the instruction writes a register.

## Implementing the Control for the RISC V Pipeline

The process of letting an instruction move from the instruction decode stage (ID) into the execution stage (EX) of this pipeline is usually called *instruction issue*; an instruction that has made this step is said to have *issued*. For the RISC V integer pipeline, all the data hazards can be checked during the ID phase of the pipeline. If a data hazard exists, the instruction is stalled before it is issued. Likewise, we can determine what forwarding will be needed during ID and set the appropriate controls then. Detecting interlocks early in the pipeline reduces the hardware complexity because the hardware never has to suspend an instruction that has updated the state of the processor, unless the entire processor is stalled. Alternatively, we can detect the hazard or forwarding at the beginning of a clock cycle that uses an operand (EX and MEM for this pipeline). To show the differences in these two approaches, we will show how the interlock for a read after write (RAW) hazard with the source coming from a load instruction (called a *load interlock*) can be implemented by a check in ID, while the implementation of forwarding paths to

| Situation                         | Example code sequence                                              | Action                                                                                                                                                   |
|-----------------------------------|--------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------|
| No dependence                     | ld x1, 45(x2)<br>add x5, x6, x7<br>sub x8, x6, x7<br>or x9, x6, x7 | No hazard possible because no dependence exists on x1 in the immediately following three instructions                                                    |
| Dependence requiring stall        | ld x1, 45(x2)<br>add x5, x1, x7<br>sub x8, x6, x7<br>or x9, x6, x7 | Comparators detect the use of x1 in the add and stall the add (and sub and or) before the add begins EX                                                  |
| Dependence overcome by forwarding | ld x1, 45(x2)<br>add x5, x6, x7<br>sub x8, x1, x7<br>or x9, x6, x7 | Comparators detect use of x1 in sub and forward result of load to ALU in time for sub to begin EX                                                        |
| Dependence with accesses in order | ld x1, 45(x2)<br>add x5, x6, x7<br>sub x8, x6, x7<br>or x9, x1, x7 | No action required because the read of x1 by or occurs in the second half of the ID phase, while the write of the loaded data occurred in the first half |

**Figure C.21** Situations that the pipeline hazard detection hardware can see by comparing the destination and sources of adjacent instructions. This table indicates that the only comparison needed is between the destination and the sources on the two instructions following the instruction that wrote the destination. In the case of a stall, the pipeline dependences will look like the third case once execution continues (dependence overcome by forwarding). Of course, hazards that involve x0 can be ignored because the register always contains 0, and the preceding test could be extended to do this.

the ALU inputs can be done during EX. [Figure C.21](#) lists the variety of circumstances that we must handle.

Let's start with implementing the load interlock. If there is a RAW hazard with the source instruction being a load, the load instruction will be in the EX stage when an instruction that needs the load data will be in the ID stage. Thus, we can describe all the possible hazard situations with a small table, which can be directly translated to an implementation. [Figure C.22](#) shows a table that detects all load interlocks when the instruction using the load result is in the ID stage.

Once a hazard has been detected, the control unit must insert the pipeline stall and prevent the instructions in the IF and ID stages from advancing. As we said earlier, all the control information is carried in the pipeline registers. (Carrying the instruction along is enough, because all control is derived from it.) Thus, when we detect a hazard we need only change the control portion of the ID/EX pipeline register to all 0s, which happens to be a no-op (an instruction that does nothing, such as `add x0, x0, x0`). In addition, we simply recirculate the contents of the IF/ID registers to hold the stalled instruction. In a pipeline with more complex hazards, the same ideas would apply: we can detect the hazard by comparing some set of pipeline registers and shift in no-ops to prevent erroneous execution.

| Opcode field of ID/EX<br>(ID/EX.IR <sub>0..5</sub> ) | Opcode field of IF/ID<br>(IF/ID.IR <sub>0..6</sub> )               | Matching operand fields           |
|------------------------------------------------------|--------------------------------------------------------------------|-----------------------------------|
| Load                                                 | Register-register ALU, load,<br>store,<br>ALU immediate, or branch | ID/EX.IR[rd] == IF/<br>ID.IR[rs1] |
| Load                                                 | Register-register ALU, or<br>branch                                | ID/EX.IR[rd] == IF/<br>ID.IR[rs2] |

**Figure C.22** The logic to detect the need for load interlocks during the ID stage of an instruction requires two comparisons, one for each possible source. Remember that the IF/ID register holds the state of the instruction in ID, which potentially uses the load result, while ID/EX holds the state of the instruction in EX, which is the load instruction.

Implementing the forwarding logic is similar, although there are more cases to consider. The key observation needed to implement the forwarding logic is that the pipeline registers contain both the data to be forwarded as well as the source and destination register fields. All forwarding logically happens from the ALU or data memory output to the ALU input, the data memory input, or the zero detection unit. Thus, we can implement the forwarding by a comparison of the destination registers of the IR contained in the EX/MEM and MEM/WB stages against the source registers of the IR contained in the ID/EX and EX/MEM registers. Figure C.23 shows the comparisons and possible forwarding operations where the destination of the forwarded result is an ALU input for the instruction currently in EX.

In addition to the comparators and combinational logic that we must determine when a forwarding path needs to be enabled, we also must enlarge the multiplexers at the ALU inputs and add the connections from the pipeline registers that are used to forward the results. Figure C.24 shows the relevant segments of the pipelined data path with the additional multiplexers and connections in place.

For RISC V, the hazard detection and forwarding hardware is reasonably simple; we will see that things become somewhat more complicated when we extend this pipeline to deal with floating point. Before we do that, we need to handle branches.

## Dealing With Branches in the Pipeline

In RISC V, conditional branches depend on comparing two register values, which we assume occurs during the EX cycle, and uses the ALU for this function. We will need to also compute the branch target address. Because testing the branch condition and determining the next PC will determine what the branch penalty is, we would like to compute both the possible PCs and choose the correct PC before the end of the EX cycle. We can do this by adding a separate adder that computes the branch target address during ID. Because the instruction is not yet decoded, we will be computing a possible target as if every instruction were a branch. This is

| Pipeline register of source instruction | Opcode of source instruction               | Pipeline register of destination instruction | Opcode of destination instruction                         | Destination of the forwarded result | Comparison (if equal then forward) |
|-----------------------------------------|--------------------------------------------|----------------------------------------------|-----------------------------------------------------------|-------------------------------------|------------------------------------|
| EX/MEM                                  | Register-register ALU, ALU immediate       | ID/EX                                        | Register-register ALU, ALU immediate, load, store, branch | Top ALU input                       | EX/MEM.IR[rd] == ID/EX.IR[rs1]     |
| EX/MEM                                  | Register-register ALU, ALU immediate       | ID/EX                                        | Register-register ALU                                     | Bottom ALU input                    | EX/MEM.IR[rd] == ID/EX.IR[rs2]     |
| MEM/WB                                  | Register-register ALU, ALU immediate, Load | ID/EX                                        | Register-register ALU, ALU immediate, load, store, branch | Top ALU input                       | MEM/WB.IR[rd] == ID/EX.IR[rs1]     |
| MEM/WB                                  | Register-register ALU, ALU immediate, Load | ID/EX                                        | Register-register ALU                                     | Bottom ALU input                    | MEM/WB.IR[rd] == ID/EX.IR[rs2]     |

**Figure C.23** Forwarding of data to the two ALU inputs (for the instruction in EX) can occur from the ALU result (in EX/MEM or in MEM/WB) or from the load result in MEM/WB. There are 10 separate comparisons needed to tell whether a forwarding operation should occur. The top and bottom ALU inputs refer to the inputs corresponding to the first and second ALU source operands, respectively, and are shown explicitly in [Figure C.18](#) on page C.30 and in [Figure C.24](#) on page C.36. Remember that the pipeline latch for destination instruction in EX is ID/EX, while the source values come from the ALUOutput portion of EX/MEM or MEM/WB or the LMD portion of MEM/WB. There is one complication not addressed by this logic: dealing with multiple instructions that write the same register. For example, during the code sequence `add x1, x2, x3; addi x1, x1, 2; sub x4, x3, x1`, the logic must ensure that the `sub` instruction uses the result of the `addi` instruction rather than the result of the `add` instruction. The logic shown here can be extended to handle this case by simply testing that forwarding from MEM/WB is enabled only when forwarding from EX/MEM is not enabled for the same input. Because the `addi` result will be in EX/MEM, it will be forwarded, rather than the `add` result in MEM/WB.

likely faster than computing the target and evaluating the condition both in EX, but does use slightly more energy.

[Figure C.25](#) shows a pipelined data path assuming the adder in ID and the evaluation of the branch condition in EX, a minor change of the pipeline structure. This pipeline will incur a two-cycle penalty on branches. In some early RISC processors, such as MIPS, the condition test on branches was restricted to allow the test to occur in ID, reducing the branch delay to one cycle. Of course, that meant that an ALU operation to a register followed by a conditional branch based on that register incurred a data hazard, which does not occur if the branch condition is evaluated in EX.

As pipeline depths increased, the branch delay increased, which made dynamic branch prediction necessary. For example, a processor with separate decode and

**Figure C.24** Forwarding of results to the ALU requires the addition of three extra inputs on each ALU multiplexer and the addition of three paths to the new inputs. The paths correspond to a bypass of: (1) the ALU output at the end of the EX, (2) the ALU output at the end of the MEM stage, and (3) the memory output at the end of the MEM stage.

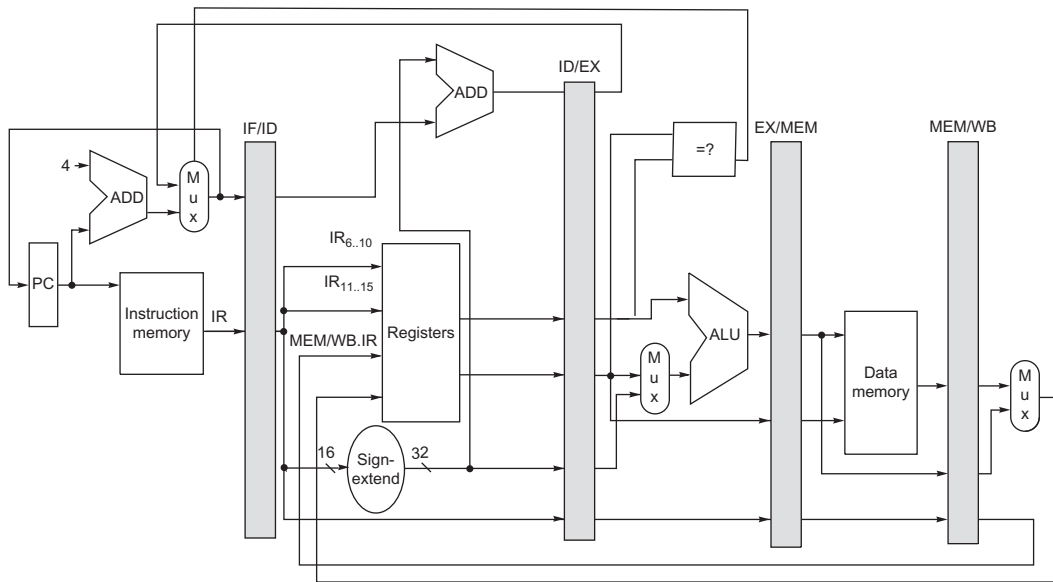

register fetch stages will probably have a branch delay that is at least 1 clock cycle longer. The branch delay, unless it is dealt with, turns into a branch penalty. Many older processors that implement more complex instruction sets have branch delays of 4 clock cycles or more, and large, deeply pipelined processors often have branch penalties of 6 or 7. Aggressive high-end superscalars, such as the Intel i7 discussed in [Chapter 3](#), may have branch penalties of 10–15 cycles! In general, the deeper the pipeline, the worse the branch penalty in clock cycles, and the more critical that branches be accurately predicted.

## C.4

## What Makes Pipelining Hard to Implement?

Now that we understand how to detect and resolve hazards, we can deal with some complications that we have avoided so far. The first part of this section considers the challenges of exceptional situations where the instruction execution order is changed in unexpected ways. In the second part of this section, we discuss some of the challenges raised by different instruction sets.

**Figure C.25** To minimize the impact of deciding whether a conditional branch is taken, we compute the branch target address in ID while doing the conditional test and final selection of next PC in EX. As mentioned in Figure C.19, the PC can be thought of as a pipeline register (e.g., as part of ID/IF), which is written with the address of the next instruction at the end of each IF cycle.

## Dealing With Exceptions

Exceptional situations are harder to handle in a pipelined processor because the overlapping of instructions makes it more difficult to know whether an instruction can safely change the state of the processor. In a pipelined processor, an instruction is executed piece by piece and is not completed for several clock cycles. Unfortunately, other instructions in the pipeline can raise exceptions that may force the processor to abort the instructions in the pipeline before they complete. Before we discuss these problems and their solutions in detail, we need to understand what types of situations can arise and what architectural requirements exist for supporting them.

### *Types of Exceptions and Requirements*

The terminology used to describe exceptional situations where the normal execution order of instruction is changed varies among processors. The terms *interrupt*, *fault*, and *exception* are used, although not in a consistent fashion. We use the term *exception* to cover all these mechanisms, including the following:

- I/O device request
- Invoking an operating system service from a user program

- Tracing instruction execution
- Breakpoint (programmer-requested interrupt)
- Integer arithmetic overflow
- FP arithmetic anomaly
- Page fault (not in main memory)
- Misaligned memory accesses (if alignment is required)
- Memory protection violation
- Using an undefined or unimplemented instruction
- Hardware malfunctions
- Power failure

When we wish to refer to some particular class of such exceptions, we will use a longer name, such as I/O interrupt, floating-point exception, or page fault.

Although we use the term *exception* to cover all of these events, individual events have important characteristics that determine what action is needed in the hardware. The requirements on exceptions can be characterized on five semi-independent axes:

1. *Synchronous versus asynchronous*—If the event occurs at the same place every time the program is executed with the same data and memory allocation, the event is *synchronous*. With the exception of hardware malfunctions, *asynchronous* events are caused by devices external to the processor and memory. Asynchronous events usually can be handled after the completion of the current instruction, which makes them easier to handle.
2. *User requested versus coerced*—If the user task directly asks for it, it is a *user-requested* event. In some sense, user-requested exceptions are not really exceptions, because they are predictable. They are treated as exceptions, however, because the same mechanisms that are used to save and restore the state are used for these user-requested events. Because the only function of an instruction that triggers this exception is to cause the exception, user-requested exceptions can always be handled after the instruction has completed. *Coerced* exceptions are caused by some hardware event that is not under the control of the user program. Coerced exceptions are harder to implement because they are not predictable.
3. *User maskable versus user nonmaskable*—If an event can be masked or disabled by a user task, it is *user maskable*. This mask simply controls whether the hardware responds to the exception or not.
4. *Within versus between instructions*—This classification depends on whether the event prevents instruction completion by occurring in the middle of execution—no matter how short—or whether it is recognized *between* instructions. Exceptions that occur *within* instructions are usually synchronous, because the instruction triggers the exception. It's harder to implement exceptions that

occur within instructions than those between instructions, because the instruction must be stopped and restarted. Asynchronous exceptions that occur within instructions arise from catastrophic situations (e.g., hardware malfunction) and always cause program termination.

5. *Resume versus terminate*—If the program’s execution always stops after the interrupt, it is a *terminating* event. If the program’s execution continues after the interrupt, it is a *resuming* event. It is easier to implement exceptions that terminate execution, because the processor need not be able to restart execution of the same program after handling the exception.

Figure C.26 classifies the preceding examples according to these five categories. The difficult task is implementing interrupts occurring within instructions where the instruction must be resumed. Implementing such exceptions requires that another program must be invoked to save the state of the executing program, correct the cause of the exception, and then restore the state of the program before the

| Exception type                                  | Synchronous vs. asynchronous | User request vs. coerced | User maskable vs. nonmaskable | Within vs. between instructions | Resume vs. terminate |
|-------------------------------------------------|------------------------------|--------------------------|-------------------------------|---------------------------------|----------------------|
| I/O device request                              | Asynchronous                 | Coerced                  | Nonmaskable                   | Between                         | Resume               |
| Invoke operating system                         | Synchronous                  | User request             | Nonmaskable                   | Between                         | Resume               |
| Tracing instruction execution                   | Synchronous                  | User request             | User maskable                 | Between                         | Resume               |
| Breakpoint                                      | Synchronous                  | User request             | User maskable                 | Between                         | Resume               |
| Integer arithmetic overflow                     | Synchronous                  | Coerced                  | User maskable                 | Within                          | Resume               |
| Floating-point arithmetic overflow or underflow | Synchronous                  | Coerced                  | User maskable                 | Within                          | Resume               |
| Page fault                                      | Synchronous                  | Coerced                  | Nonmaskable                   | Within                          | Resume               |
| Misaligned memory accesses                      | Synchronous                  | Coerced                  | User maskable                 | Within                          | Resume               |
| Memory protection violations                    | Synchronous                  | Coerced                  | Nonmaskable                   | Within                          | Resume               |
| Using undefined instructions                    | Synchronous                  | Coerced                  | Nonmaskable                   | Within                          | Terminate            |
| Hardware malfunctions                           | Asynchronous                 | Coerced                  | Nonmaskable                   | Within                          | Terminate            |
| Power failure                                   | Asynchronous                 | Coerced                  | Nonmaskable                   | Within                          | Terminate            |

**Figure C.26** Five categories are used to define what actions are needed for the different exception types. Exceptions that must allow resumption are marked as resume, although the software may often choose to terminate the program. Synchronous, coerced exceptions occurring within instructions that can be resumed are the most difficult to implement. We might expect that memory protection access violations would always result in termination; however, modern operating systems use memory protection to detect events such as the first attempt to use a page or the first write to a page. Thus, processors should be able to resume after such exceptions.

instruction that caused the exception can be tried again. This process must be effectively invisible to the executing program. If a pipeline provides the ability for the processor to handle the exception, save the state, and restart without affecting the execution of the program, the pipeline or processor is said to be *restartable*. While early supercomputers and microprocessors often lacked this property, almost all processors today support it, at least for the integer pipeline, because it is needed to implement virtual memory (see [Chapter 2](#)).

### *Stopping and Restarting Execution*

As in unpipelined implementations, the most difficult exceptions have two properties: (1) they occur within instructions (that is, in the middle of the instruction execution corresponding to EX or MEM pipe stages), and (2) they must be restartable. In our RISC V pipeline, for example, a virtual memory page fault resulting from a data fetch cannot occur until sometime in the MEM stage of the instruction. By the time that fault is seen, several other instructions will be in execution. A page fault must be restartable and requires the intervention of another process, such as the operating system. Thus, the pipeline must be safely shut down and the state saved so that the instruction can be restarted in the correct state. Restarting is usually implemented by saving the PC of the instruction at which to restart. If the restarted instruction is not a branch, then we will continue to fetch the sequential successors and begin their execution in the normal fashion. If the restarted instruction is a branch, then we will reevaluate the branch condition and begin fetching from either the target or the fall-through. When an exception occurs, the pipeline control can take the following steps to save the pipeline state safely:

1. Force a trap instruction into the pipeline on the next IF.
2. Until the trap is taken, turn off all writes for the faulting instruction and for all instructions that follow in the pipeline; this can be done by placing zeros into the pipeline latches of all instructions in the pipeline, starting with the instruction that generates the exception, but not those that precede that instruction. This prevents any state changes for instructions that will not be completed before the exception is handled.
3. After the exception-handling routine in the operating system receives control, it immediately saves the PC of the faulting instruction. This value will be used to return from the exception later.

After the exception has been handled, special instructions return the processor from the exception by reloading the PCs and restarting the instruction stream (using the exception return in RISC V). If the pipeline can be stopped so that the instructions just before the faulting instruction are completed and those after it can be restarted from scratch, the pipeline is said to have *precise exceptions*. Ideally, the faulting instruction would not have changed the state, and correctly handling some exceptions requires that the faulting instruction have no effects. For other exceptions,

such as floating-point exceptions, the faulting instruction on some processors writes its result before the exception can be handled. In such cases, the hardware must be prepared to retrieve the source operands, even if the destination is identical to one of the source operands. Because floating-point operations may run for many cycles, it is highly likely that some other instruction may have written the source operands (as we will see in the next section, floating-point operations often complete out of order). To overcome this, many recent high-performance processors have introduced two modes of operation. One mode has precise exceptions and the other (fast or performance mode) does not. Of course, the precise exception mode is slower, since it allows less overlap among floating-point instructions.

Supporting precise exceptions is a requirement in many systems, while in others it is “just” valuable because it simplifies the operating system interface. At a minimum, any processor with demand paging or IEEE arithmetic trap handlers must make its exceptions precise, either in the hardware or with some software support. For integer pipelines, the task of creating precise exceptions is easier, and accommodating virtual memory strongly motivates the support of precise exceptions for memory references. In practice, these reasons have led designers and architects to always provide precise exceptions for the integer pipeline. In this section we describe how to implement precise exceptions for the RISC V integer pipeline. We will describe techniques for handling the more complex challenges arising in the floating-point pipeline in [Section C.5](#).

*Exceptions in RISC V*

[Figure C.27](#) shows the RISC V pipeline stages and which problem exceptions might occur in each stage. With pipelining, multiple exceptions may occur in the same clock cycle because there are multiple instructions in execution. For example, consider this instruction sequence:

|     |    |    |    |     |     |    |
|-----|----|----|----|-----|-----|----|
| ld  | IF | ID | EX | MEM | WB  |    |
| add |    | IF | ID | EX  | MEM | WB |

| Pipeline stage | Problem exceptions occurring                                                           |
|----------------|----------------------------------------------------------------------------------------|
| IF             | Page fault on instruction fetch; misaligned memory access; memory protection violation |
| ID             | Undefined or illegal opcode                                                            |

**Figure C.27** Exceptions that may occur in the RISC V pipeline. Exceptions raised from instruction or data memory access account for six out of eight cases.

This pair of instructions can cause a data page fault and an arithmetic exception at the same time, because the `ld` is in the MEM stage while the `add` is in the EX stage. This case can be handled by dealing with only the data page fault and then restarting the execution. The second exception will reoccur (but not the first, if the software is correct), and when the second exception occurs it can be handled independently.

In reality, the situation is not as straightforward as this simple example. Exceptions may occur out of order; that is, an instruction may cause an exception before an earlier instruction causes one. Consider again the preceding sequence of instructions, `ld` followed by `add`. The `ld` can get a data page fault, seen when the instruction is in MEM, and the `add` can get an instruction page fault, seen when the `add` instruction is in IF. The instruction page fault will actually occur first, even though it is caused by a later instruction!

Because we are implementing precise exceptions, the pipeline is required to handle the exception caused by the `ld` instruction first. To explain how this works, let's call the instruction in the position of the `ld` instruction  $i$ , and the instruction in the position of the `add` instruction  $i+1$ . The pipeline cannot simply handle an exception when it occurs in time, because that will lead to exceptions occurring out of the unpipelined order. Instead, the hardware posts all exceptions caused by a given instruction in a status vector associated with that instruction. The exception status vector is carried along as the instruction goes down the pipeline. Once an exception indication is set in the exception status vector, any control signal that may cause a data value to be written is turned off (this includes both register writes and memory writes). Because a store can cause an exception during MEM, the hardware must be prepared to prevent the store from completing if it raises an exception.

When an instruction enters WB (or is about to leave MEM), the exception status vector is checked. If any exceptions are posted, they are handled in the order in which they would occur in time on an unpipelined processor—the exception corresponding to the earliest instruction (and usually the earliest pipe stage for that instruction) is handled first. This guarantees that all exceptions will be seen on instruction  $i$  before any are seen on  $i+1$ . Of course, any action taken in earlier pipe stages on behalf of instruction  $i$  may be invalid, but because writes to the register file and memory were disabled, no state could have been changed. As we will see in [Section C.5](#), maintaining this precise model for FP operations is much harder.

In the next subsection we describe problems that arise in implementing exceptions in the pipelines of processors with more powerful, longer-running instructions.

## Instruction Set Complications

No RISC V instruction has more than one result, and our RISC V pipeline writes that result only at the end of an instruction's execution. When an instruction is guaranteed to complete, it is called *committed*. In the RISC V integer pipeline, all instructions are committed when they reach the end of the MEM stage (or beginning of WB) and no instruction updates the state before that stage. Thus, precise exceptions

are straightforward. Some processors have instructions that change the state in the middle of the instruction execution, before the instruction and its predecessors are guaranteed to complete. For example, autoincrement addressing modes in the IA-32 architecture cause the update of registers in the middle of an instruction execution. In such a case, if the instruction is aborted because of an exception, it will leave the processor state altered. Although we know which instruction caused the exception, without additional hardware support the exception will be imprecise because the instruction will be half finished. Restarting the instruction stream after such an imprecise exception is difficult. Alternatively, we could avoid updating the state before the instruction commits, but this may be difficult or costly, because there may be dependences on the updated state: consider a VAX instruction that autoincrements the same register multiple times. Thus, to maintain a precise exception model, most processors with such instructions have the ability to back out any state changes made before the instruction is committed. If an exception occurs, the processor uses this ability to reset the state of the processor to its value before the interrupted instruction started. In the next section, we will see that a more powerful RISC V floating-point pipeline can introduce similar problems, and [Section C.7](#) introduces techniques that substantially complicate exception handling.

A related source of difficulties arises from instructions that update memory state during execution, such as the string copy operations on the Intel architecture or IBM 360 (see Appendix K). To make it possible to interrupt and restart these instructions, the instructions are defined to use the general-purpose registers as working registers. Thus, the state of the partially completed instruction is always in the registers, which are saved on an exception and restored after the exception, allowing the instruction to continue.

A different set of difficulties arises from odd bits of state that may create additional pipeline hazards or may require extra hardware to save and restore. Condition codes are a good example of this. Many processors set the condition codes implicitly as part of the instruction. This approach has advantages, because condition codes decouple the evaluation of the condition from the actual branch. However, implicitly set condition codes can cause difficulties in scheduling any pipeline delays between setting the condition code and the branch, because most instructions set the condition code and cannot be used in the delay slots between the condition evaluation and the branch.

Additionally, in processors with condition codes, the processor must decide when the branch condition is fixed. This involves finding out when the condition code has been set for the last time before the branch. In most processors with implicitly set condition codes, this is done by delaying the branch condition evaluation until all previous instructions have had a chance to set the condition code.

Of course, architectures with explicitly set condition codes allow the delay between condition test and the branch to be scheduled; however, pipeline control must still track the last instruction that sets the condition code to know when the branch condition is decided. In effect, the condition code must be treated as an operand that requires hazard detection for RAW hazards with branches, just as RISC V must do on the registers.

A final thorny area in pipelining is multicycle operations. Imagine trying to pipeline a sequence of x86 instructions such as this:

```

mov BX, AX ; moves between registers
add 42(BX+SI), BX ; adds memory contents and register
 ; to same memory location
sub BX, AX ; subtracts registers
rep movsb ; moves a character string of
 ; length given by register CX

```

Although none of these instructions is particularly long (an x86 instruction can be up to 15 bytes), they do differ radically in the number of clock cycles they will require, from as low as one up to hundreds of clock cycles. These instructions also require different numbers of data memory accesses, from zero to possibly hundreds. The data hazards are very complex and occur both between and within instructions (nothing prevents the `movsb` from having an overlapping source and destination!). The simple solution of making all instructions execute for the same number of clock cycles is unacceptable because it introduces an enormous number of hazards and bypass conditions and makes an immensely long pipeline. Pipelining the x86 at the instruction level is difficult, but a clever solution was found, similar to one used for the VAX. They pipeline the *microinstruction* execution; a microinstruction is a simple instruction used in sequences to implement a more complex instruction set. Because the microinstructions are simple (they look a lot like RISC V), the pipeline control is much easier. Since 1995, all Intel IA-32 microprocessors have used this strategy of converting the IA-32 instructions into microoperations, and then pipelining the microoperations. In fact, this approach is even used for some of the more complex instructions in the ARM architecture.

In comparison, load-store processors have simple operations with similar amounts of work and pipeline more easily. If architects realize the relationship between instruction set design and pipelining, they can design architectures for more efficient pipelining. In the next section, we will see how the RISC V pipeline deals with long-running instructions, specifically floating-point operations.

For many years, the interaction between instruction sets and implementations was believed to be small, and implementation issues were not a major focus in designing instruction sets. In the 1980s, it became clear that the difficulty and inefficiency of pipelining could both be increased by instruction set complications. In the 1990s, all companies moved to simpler instructions sets with the goal of reducing the complexity of aggressive implementations.

## C.5

### Extending the RISC V Integer Pipeline to Handle Multicycle Operations

We now want to explore how our RISC V pipeline can be extended to handle floating-point operations. This section concentrates on the basic approach and

the design alternatives, closing with some performance measurements of a RISC V floating-point pipeline.

It is impractical to require that all RISC V FP operations complete in 1 clock cycle, or even in 2. Doing so would mean accepting a slow clock or using enormous amounts of logic in the FP units, or both. Instead, the FP pipeline will allow for a longer latency for operations. This is easier to grasp if we imagine the FP instructions as having the same pipeline as the integer instructions, with two important changes. First, the EX cycle may be repeated as many times as needed to complete the operation—the number of repetitions can vary for different operations. Second, there may be multiple FP functional units. A stall will occur if the instruction to be issued will cause either a structural hazard for the functional unit it uses or a data hazard.

For this section, let's assume that there are four separate functional units in our RISC V implementation:

1. The main integer unit that handles loads and stores, integer ALU operations, and branches
2. FP and integer multiplier
3. FP adder that handles FP add, subtract, and conversion
4. FP and integer divider

If we also assume that the execution stages of these functional units are not pipelined, then [Figure C.28](#) shows the resulting pipeline structure. Because EX is not pipelined, no other instruction using that functional unit may issue until the previous instruction leaves EX. Moreover, if an instruction cannot proceed to the EX stage, the entire pipeline behind that instruction will be stalled.

In reality, the intermediate results are probably not cycled around the EX unit as [Figure C.28](#) suggests; instead, the EX pipeline stage has some number of clock delays larger than 1. We can generalize the structure of the FP pipeline shown in [Figure C.28](#) to allow pipelining of some stages and multiple ongoing operations. To describe such a pipeline, we must define both the latency of the functional units and also the *initiation interval* or *repeat interval*. We define latency the same way we defined it earlier: the number of intervening cycles between an instruction that produces a result and an instruction that uses the result. The initiation or repeat interval is the number of cycles that must elapse between issuing two operations of a given type. For example, we will use the latencies and initiation intervals shown in [Figure C.29](#).
